

# **CLINICAL GASTROINTESTINAL ENDOSCOPY**

THIRD EDITION

## **Vinay Chandrasekhara, MD**

Senior Associate Consultant  
Division of Gastroenterology & Hepatology  
Mayo Clinic  
Rochester, Minnesota

## **B. Joseph Elmunzer, MD, MSc**

The Peter B. Cotton Endowed Chair in Endoscopic Innovation  
Associate Professor of Internal Medicine  
Division of Gastroenterology and Hepatology  
Medical University of South Carolina  
Charleston, South Carolina

## **Mouen A. Khashab, MD**

Associate Professor of Medicine  
Director of Therapeutic Endoscopy  
Division of Gastroenterology and Hepatology  
Johns Hopkins Hospital  
Baltimore, Maryland

## **V. Raman Muthusamy, MD, MAS**

Director of Endoscopy, UCLA Health System  
Professor of Clinical Medicine  
Vatche and Tamar Manoukian Division of Digestive Diseases  
David Geffen School of Medicine at UCLA  
Los Angeles, California

## Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

# CONTRIBUTORS

**James L. Achord, MD**

Professor Emeritus  
University of Mississippi Medical Center  
Jackson, Mississippi  
1: The History of Gastrointestinal Endoscopy

**Michelle J. Alfa, BSc, MSc, PhD**

Principal Investigator  
St. Boniface Research Centre;  
Professor  
Department of Medical Microbiology  
University of Manitoba  
Winnipeg, Manitoba, Canada  
4: Cleaning and Disinfecting Gastrointestinal Endoscopy Equipment

**Mohammad Al-Haddad, MD, MSc, FASGE, FACG, AGAF**

Associate Professor of Medicine  
Division of Gastroenterology and Hepatology  
Indiana University School Medicine  
Indianapolis, Indiana  
62: Evaluation and Staging of Pancreaticobiliary Malignancy

**Andrea Anderloni, MD, PhD**

Digestive Endoscopy Unit  
Division of Gastroenterology  
Humanitas Research Hospital  
Milan, Italy  
28: Palliation of Malignant Dysphagia and Esophageal Fistulas

**Joseph C. Anderson, MD**

Associate Professor of Medicine  
Department of Veterans Affairs Medical Center  
White River Junction, Vermont;  
The Geisel School of Medicine at Dartmouth  
Hanover, New Hampshire;  
Division of Gastroenterology and Hepatology  
University of Connecticut School of Medicine  
Farmington, Connecticut  
36: Colorectal Cancer Screening and Surveillance

**Anna Baiges, MD**

Hepatic Hemodynamic Laboratory  
Liver Unit, Hospital Clinic  
Barcelona, Spain  
15: Portal Hypertensive Bleeding

**John Baillie, MD**

Professor  
Division of Gastroenterology and Hepatology  
Department of Medicine  
Virginia Commonwealth University School of Medicine  
Richmond, Virginia  
3: How Endoscopes Work

**Alan N. Barkun, MD, MSc**

Division of Gastroenterology  
McGill University Health Center  
Montreal, Québec, Canada  
14: Nonvariceal Upper Gastrointestinal Bleeding

**Todd H. Baron, MD, FASGE**

Professor of Medicine  
Division of Gastroenterology and Hepatology  
University of North Carolina  
Chapel Hill, North Carolina  
20: Endoscopic Diagnosis and Management of Zenker's Diverticula

**Omer Basar, MD**

Pancreas Biliary Center, Gastrointestinal Unit  
Massachusetts General Hospital  
Boston, Massachusetts;  
Professor of Medicine  
Department of Gastroenterology  
Hacettepe University  
Ankara, Turkey  
61: Pancreatic Cystic Lesions

**Mark Benson, MD**

Assistant Professor  
Division of Gastroenterology and Hepatology  
University of Wisconsin School of Medicine and Public Health  
Madison, Wisconsin  
22: Ingested Foreign Objects and Food Bolus Impactions

**Lyz Bezerra Silva, MD, MSC**

Associate Professor of Surgery  
Department of Surgery  
Federal University of Pernambuco  
Recife, Brazil  
45: Intramural and Transmural Endoscopy

**Stas Bezobchuk, MD**

Institute of Gastroenterology, Hepatology, and Nutrition  
Emek Medical Center  
Afula, Israel  
17: Middle Gastrointestinal Bleeding

**Kenneth F. Binmoeller, MD**

Director, Interventional Endoscopy Services  
Paul May and Frank Stein Interventional Endoscopy Center  
California Pacific Medical Center  
San Francisco, California  
58: Pancreatic Fluid Collections and Leaks

**Sarah Blankstein, AB, JD**

Boston, Massachusetts  
10: Legal Concepts for Gastroenterologists

**Daniel Blero, MD, PhD**

Department of Gastroenterology  
Chu Charleroi  
Charleroi, Belgium;  
Hôpital Erasme  
Brussels, Belgium  
43: Endoscopic Techniques for Weight Loss

**Michael J. Bourke, BSc, MD**

Department of Gastroenterology and Hepatology  
Westmead Hospital  
Sydney, Australia  
34: Duodenal and Papillary Adenomas

**William R. Brugge, MD**

Chief  
Division of Gastroenterology  
Mount Auburn Hospital  
Cambridge, Massachusetts  
61: Pancreatic Cystic Lesions

**Marco J. Bruno, MD, PhD**

Department of Gastroenterology and Hepatology  
Erasmus Medical Center  
University of Rotterdam  
Rotterdam, The Netherlands  
63: Palliation of Malignant Pancreaticobiliary Obstruction

**Anna M. Buchner, MD, PhD**

Assistant Professor of Medicine  
Division of Gastroenterology  
University of Pennsylvania  
Philadelphia, Pennsylvania  
38: Endoscopic Diagnosis and Staging of Inflammatory Bowel Disease

- Andrés Cárdenas, MD, MMSc, PhD,  
AGAF, FAASLD**  
Faculty Member/Consultant  
Institute of Digestive Diseases and  
Metabolism Hospital Clinic  
University of Barcelona  
Barcelona, Spain  
15: Portal Hypertensive Bleeding  
54: Postoperative Biliary Strictures and Leaks
- David Carr-Locke, MD, FRCP, FASGE,  
AGAF, NYSGEF**  
Clinical Director  
Center for Advanced Digestive Care  
Gastroenterology & Hepatology  
Weill Cornell Medical College  
Cornell University  
New York, New York  
55: Infections of the Biliary Tract
- Kenneth Chang, MD**  
Professor and Chief  
Division of Gastroenterology and  
Hepatology  
University of California—Irvine  
Orange, California  
51: Endoscopic Ultrasound and Fine-Needle  
Aspiration for Pancreatic and Biliary  
Disorders
- Saurabh Chawla, MD, FACG**  
Director of Endoscopy  
Grady Memorial Hospital;  
Assistant Professor of Medicine  
Emory University School of Medicine  
Atlanta, Georgia  
48: Preparation for Pancreaticobiliary  
Endoscopy
- John O. Clarke, MD**  
Clinical Associate Professor  
Department of Medicine  
Stanford University  
Stanford, California  
19: Esophageal Motility Disorders  
29: Endoscopic Approaches for Gastroparesis
- Jonathan Cohen, MD**  
Clinical Professor  
Department of Medicine  
New York University Langone School of  
Medicine  
New York, New York  
13: Endoscopic Simulators
- Andrew P. Copland, MD**  
Assistant Professor of Medicine  
Division of Gastroenterology and  
Hepatology  
University of Virginia Health Systems  
Charlottesville, Virginia  
40: Colonic Strictures
- Guido Costamagna, MD, FACG**  
Digestive Endoscopy Unit  
Catholic University  
Gemelli University Hospital  
Rome, Italy  
54: Postoperative Biliary Strictures  
and Leaks
- Peter B. Cotton, MD, FRCS, FRCP**  
Professor of Medicine  
Digestive Disease Center  
Medical University of South Carolina  
Charleston, South Carolina  
56: Sphincter of Oddi Disorders
- Amit P. Desai, MD**  
Texas Digestive Diseases Consultants  
Texas Health Presbyterian Hospital  
Dallas, Texas  
47: Extraintestinal Endosonography
- Jacques Devière, MD, PhD**  
Professor of Medicine  
Chairman, Department of Gastroenterology,  
Hepatopancreatology, and Digestive  
Oncology  
Erasme Hospital  
Université Libre de Bruxelles  
Brussels, Belgium  
43: Endoscopic Techniques for  
Weight Loss
- Christopher J. DiMaio, MD**  
Director of Therapeutic Endoscopy  
Associate Professor of Medicine  
Division of Gastroenterology  
Icahn School of Medicine at Mount Sinai  
New York, New York  
53: Gallstone Disease: Choledocholithiasis,  
Cholecystitis, and Gallstone Pancreatitis
- Peter Draganov, MD**  
Professor of Medicine  
Department of Internal Medicine  
University of Florida  
Gainesville, Florida  
37: Colonoscopic Polypectomy,  
Mucosal Resection, and Submucosal  
Dissection
- Jérôme Dumortier, MD**  
Department of Hepatogastroenterology and  
Digestive Endoscopy  
Edouard Herriot Hospital  
Lyon, France  
11: Small-Caliber Endoscopy
- Jeffrey J. Easler, MD**  
Assistant Professor of Medicine  
Division of Gastroenterology and  
Hepatology  
Indiana University School of Medicine;  
Richard L. Roudebush VA Medical Center  
Indianapolis, Indiana  
49: Cholangiography and Pancreatography
- Gary W. Falk, MD, MS**  
Professor of Medicine  
Department of Medicine, Division of  
Gastroenterology  
University of Pennsylvania Perelman School  
of Medicine  
Philadelphia, Pennsylvania  
25: Barrett's Esophagus: Diagnosis,  
Surveillance, and Medical Management
- Francis A. Farrelly, MD, MSc**  
Clinical Director  
Section of Gastroenterology  
Boston Medical Center;  
Professor of Medicine  
Department of Medicine  
Boston University School of Medicine  
Boston, Massachusetts  
39: Dysplasia Surveillance in Inflammatory  
Bowel Disease
- Andrew Feld, MD, JD**  
Program Chief, Group Health Cooperative  
Clinical Professor  
University of Washington  
Seattle, Washington  
10: Legal Concepts for Gastroenterologists
- Kayla Feld, JD**  
Quinn Emanuel Urquhart & Sullivan  
Washington, D.C.  
10: Legal Concepts for Gastroenterologists
- Paul Fockens, MD, PhD, FASGE**  
Professor and Chair  
Department of Gastroenterology and  
Hepatology  
Academic Medical Center  
Amsterdam, The Netherlands  
33: Palliation of Gastric Outlet Obstruction
- Evan L. Fogel, MD, MSc, FRCP(C)**  
Professor of Medicine  
Department of Gastroenterology and  
Hepatology  
Indiana University School of Medicine  
Indianapolis, Indiana  
49: Cholangiography and Pancreatography

**Kyle J. Fortinsky, MD, BSc**

Division of Gastroenterology  
University of Toronto  
Toronto, Ontario, Canada  
14: Nonvariceal Upper Gastrointestinal Bleeding

**Martin L. Freeman, MD**

Professor of Medicine  
Division of Gastroenterology, Hepatology, and Nutrition  
University of Minnesota  
Minneapolis, Minnesota  
57: Recurrent Acute Pancreatitis

**Juan Carlos García-Pagán, MD, PhD**

Head  
Barcelona Hepatic Hemodynamic Lab;  
Senior Consultant in Hepatology  
Associate Professor  
University of Barcelona;  
Liver Unit, Hospital Clínic  
Barcelona, Spain  
15: Portal Hypertensive Bleeding

**Hans Gerdes, MD**

Attending Physician  
Department of Medicine  
Memorial Sloan Kettering Cancer Center;  
Professor of Clinical Medicine  
Weill Cornell Medical College of Cornell University  
New York, New York  
30: Gastric Polyps and Thickened Gastric Folds

**Joanna A. Gibson, MD, PhD**

Assistant Professor of Pathology  
Yale University School of Medicine  
New Haven, Connecticut  
5: Tissue Sampling, Specimen Handling, and Laboratory Processing

**Gregory G. Ginsberg, MD**

Professor of Medicine  
Department of Medicine, Division of Gastroenterology  
Hospital of the University of Pennsylvania  
Philadelphia, Pennsylvania  
50: Difficult Cannulation and Sphincterotomy

**Marc Giovannini, MD**

Head, Gastroenterology and Endoscopy Department  
Paoli-Calmettes Institute  
Marseille, France  
52: Endoscopic Ultrasound-Guided Access and Drainage of the Pancreaticobiliary Ductal Systems

**Ian M. Gralnek, MD, MSHS, FASGE**

Clinical Associate Professor of Medicine/Gastroenterology  
Rappaport Faculty of Medicine Technion Israel Institute of Technology;  
Chief, Institute of Gastroenterology, Hepatology and Nutrition  
Emek Medical Center  
Afula, Israel  
17: Middle Gastrointestinal Bleeding

**Frank G. Gress, MD**

Professor of Medicine  
Chief, Interventional Endoscopy  
Division of Digestive & Liver Diseases  
Columbia University Medical Center  
New York, New York  
47: Extraintestinal Endosonography

**Robert H. Hawes, MD**

Professor  
Department of Medicine  
University of Central Florida College of Medicine;  
Medical Director  
Florida Hospital Institute for Minimally Invasive Therapy  
Florida Hospital Orlando  
Orlando, Florida  
59: Chronic Pancreatitis

**Virginia Hernández-Gea, MD, PhD**

Hepatic Hemodynamic Laboratory  
Liver Unit, Hospital Clínic  
Barcelona, Spain  
15: Portal Hypertensive Bleeding

**Ikuro Hirano, MD**

Professor of Medicine  
Department of Medicine, Division of Gastroenterology  
Northwestern University Feinberg School of Medicine;  
Director, Northwestern Esophageal Center  
Northwestern Medicine  
Chicago, Illinois  
23: Eosinophilic Esophagitis

**Jürgen Hochberger, MD, PhD**

Chairman  
Department of Gastroenterology  
Vivantes Klinikum im Friedrichshain Berlin, Germany  
50: Difficult Cannulation and Sphincterotomy

**Douglas A. Howell, MD**

Director, Advanced Interventional Endoscopy Fellowship  
Director, Pancreaticobiliary Center  
Maine Medical Center  
Portland, Maine;  
Associate Clinical Professor  
Tufts University School of Medicine  
Boston, Massachusetts  
60: The Indeterminate Biliary Stricture

**Chin Hur, MD, MPH**

Associate Director, Institute for Technology Assessment  
Director, GI Health Outcomes Research  
Massachusetts General Hospital;  
Associate Professor of Medicine  
Harvard Medical School  
Boston, Massachusetts  
26: Screening for Esophageal Squamous Cell Carcinoma

**Joo Ha Hwang, MD, PhD**

Professor of Medicine  
Department of Medicine  
Division of Gastroenterology and Hepatology  
Stanford University  
Stanford, California  
6: Electrosurgery in Therapeutic Endoscopy

**Maite Betés Ibañez, PhD, MD**

Department of Gastroenterology  
University Clinic of Navarra  
Pamplona, Navarra, Spain  
18: Occult and Unexplained Chronic Gastrointestinal Bleeding

**Takao Itoi, MD, PhD, FASGE, FACG**

Chair and Professor  
Department of Gastroenterology and Hepatology  
Tokyo Medical University  
Tokyo, Japan  
52: Endoscopic Ultrasound-Guided Access and Drainage of the Pancreaticobiliary Ductal Systems

**Prasad G. Iyer, MD, MS**

Professor and Consultant  
Department of Gastroenterology and Hepatology  
Mayo Clinic  
Rochester, Minnesota  
27: Endoscopic Treatment of Early Esophageal Neoplasia

**David A. Johnson, MD, MACG, FASGE, FACP**  
 Professor of Medicine and Chief  
 Division of Gastroenterology and  
 Hepatology  
 Department of Internal Medicine  
 Eastern Virginia Medical School  
 Norfolk, Virginia  
 9: Bowel Preparation for Colonoscopy

**Sreeni Jonnalagadda, MD**  
 Professor of Medicine  
 Director of Therapeutic and Biliary  
 Endoscopy  
 Saint Luke's Hospital  
 University of Missouri—Kansas City  
 Kansas City, Missouri  
 12: Postsurgical Endoscopic Anatomy

**Charles J. Kahi, MD, MS, FACP, FACG, AGAF, FASGE**  
 Professor of Clinical Medicine  
 Indiana University School of Medicine;  
 Gastroenterology Section Chief  
 Richard L. Roudebush VA Medical Center  
 Indianapolis, Indiana  
 36: Colorectal Cancer Screening and  
 Surveillance

**Tonya Kaltenbach, MD, MAS**  
 Associate Professor of Clinical Medicine  
 Division of Gastroenterology, Department of  
 Medicine  
 University California San Francisco;  
 Director of Advanced Endoscopy  
 San Francisco Veterans Affairs Medical Center  
 San Francisco, California  
 37: Colonoscopic Polypectomy, Mucosal  
 Resection, and Submucosal Dissection

**Leila Kia, MD**  
 Assistant Professor of Medicine  
 Department of Medicine, Division of  
 Gastroenterology  
 Northwestern University Feinberg School of  
 Medicine  
 Chicago, Illinois  
 23: Eosinophilic Esophagitis

**Michael B. Kimmey, MD**  
 Franciscan Digestive Care Associates  
 Gig Harbor, Washington  
 35: Acute Colonic Pseudo-Obstruction

**Amir Klein, MD**  
 Department of Gastroenterology and  
 Hepatology  
 Rambam Health Care Campus  
 Haifa, Israel  
 34: Duodenal and Papillary Adenomas

**Michael L. Kochman, MD**  
 Wilmott Family Professor of Medicine  
 Division of Gastroenterology, Department of  
 Medicine  
 Perelman School of Medicine  
 University of Pennsylvania  
 Philadelphia, Pennsylvania  
 21: Benign Esophageal Strictures

**Divyanshu R. Kohli, MD**  
 Division of Gastroenterology and  
 Hepatology  
 Department of Medicine  
 Virginia Commonwealth University School  
 of Medicine  
 Richmond, Virginia  
 3: How Endoscopes Work

**Andrew Korman**  
 Division of Gastroenterology and  
 Hepatology  
 Saint Peter's University Hospital  
 New Brunswick, New Jersey  
 55: Infections of the Biliary Tract

**Wilson T. Kwong, MD, MS**  
 Assistant Professor  
 Department of Gastroenterology  
 University of California San Diego  
 La Jolla, California  
 16: Lower Gastrointestinal Bleeding

**Ryan Law, DO**  
 Clinical Lecturer  
 Division of Gastroenterology and  
 Hepatology  
 University of Michigan  
 Ann Arbor, Michigan  
 20: Endoscopic Diagnosis and Management  
 of Zenker's Diverticula

**David A. Leiman, MD, MSHP**  
 Assistant Professor of Medicine  
 Division of Gastroenterology  
 Duke University School of Medicine  
 Durham, North Carolina  
 24: Gastroesophageal Reflux Disease

**Anne Marie Lennon, MB, PhD, FRCPI**  
 Benjamin Baker Scholar  
 Associate Professor of Medicine and Surgery  
 The Johns Hopkins Hospital  
 Baltimore, Maryland  
 61: Pancreatic Cystic Lesions

**Michael Levy, MD**  
 Professor of Medicine  
 Division of Gastroenterology and  
 Hepatology  
 Mayo Clinic  
 Rochester, Minnesota  
 62: Evaluation and Staging of  
 Pancreaticobiliary Malignancy

**David Lichtenstein, MD**  
 Director of Endoscopy  
 Department of Gastroenterology  
 Boston Medical Center  
 Boston University School of Medicine  
 Boston, Massachusetts  
 4: Cleaning and Disinfecting Gastrointestinal  
 Endoscopy Equipment

**Gary R. Lichtenstein, MD**  
 Professor of Medicine  
 Director, Center for Inflammatory Bowel  
 Disease  
 Division of Gastroenterology  
 University of Pennsylvania  
 Philadelphia, Pennsylvania  
 38: Endoscopic Diagnosis and Staging of  
 Inflammatory Bowel Disease

**Alisa Likhitsup, MD**  
 Gastroenterology Fellow  
 Department of Gastroenterology  
 University of Missouri—Kansas City  
 Kansas City, Missouri  
 12: Postsurgical Endoscopic Anatomy

**Jimmy K. Liundi, MBBS, FRCP, FRCPE, FACG**  
 Consultant Gastroenterologist  
 Department of Gastroenterology  
 The Pennine Acute Hospitals NHS Trust;  
 Honorary Senior Lecturer  
 Institute of Inflammation and Repair  
 University of Manchester  
 Manchester, United Kingdom  
 39: Dysplasia Surveillance in Inflammatory  
 Bowel Disease

**Gianluca Lollo, MD**  
 Department of Surgical Oncology and  
 Gastroenterological Sciences  
 University of Padua  
 Padua, Italy  
 28: Palliation of Malignant Dysphagia and  
 Esophageal Fistulas

**Fauze Maluf-Filho, MD, PhD, FASGE**  
Professor  
Department of Gastroenterology  
Medical School of University of São Paulo;  
Chief  
Endoscopy Unit  
Institute of Cancer of University of São  
Paulo  
63: Palliation of Malignant Pancreaticobiliary  
Obstruction

**Jennifer Maranki, MD, MSc**  
Associate Professor of Medicine  
Director of Endoscopy  
Division of Gastroenterology and  
Hepatology  
Penn State Hershey Medical Center  
Hershey, Pennsylvania  
46: Endoscopic Full-Thickness Resection of  
Subepithelial Lesions of the GI Tract

**Richard W. McCallum, MD, FACP,  
FRACP (Aust), FACG, AGAF**  
Professor of Medicine and Founding Chair  
Department of Internal Medicine  
Texas Tech University  
El Paso, Texas;  
Honorary Professor  
University of Queensland  
Queensland, Australia  
29: Endoscopic Approaches for Gastroparesis

**Stephen A. McClave, MD**  
Professor of Medicine  
Department of Medicine  
University of Louisville School of Medicine  
Louisville, Kentucky  
42: Techniques in Enteral Access

**Klaus Mergener, MD, PhD, MBA**  
Partner  
Digestive Health Specialists  
Tacoma, Washington  
2: Setting Up an Endoscopy Facility

**David C. Metz, MD**  
Professor of Medicine  
Division of Gastroenterology  
Perelman School of Medicine  
University of Pennsylvania  
Philadelphia, Pennsylvania  
24: Gastroesophageal Reflux Disease

**Volker Meves, MD**  
Department of Gastroenterology  
Vivantes Klinikum im Friedrichshain  
Berlin, Germany  
50: Difficult Cannulation and  
Sphincterotomy

**Marcia L. Morris, MS**  
Electrosurgery Consultant  
St. Paul, Minnesota  
6: Electrosurgery in Therapeutic Endoscopy

**Daniel K. Mullady, MD**  
Associate Professor of Medicine  
Director, Interventional Endoscopy  
Department of Gastroenterology  
Washington University in St. Louis School of  
Medicine  
St. Louis, Missouri  
53: Gallstone Disease: Choledocholithiasis,  
Cholecystitis, and Gallstone Pancreatitis

**Miguel Muñoz-Nava, PhD, MD**  
Professor of Medicine  
University of Navarra School of Medicine;  
Director  
Department of Gastroenterology  
University of Navarra Clinic  
Pamplona, Navarra, Spain  
18: Occult and Unexplained Chronic  
Gastrointestinal Bleeding

**V. Raman Muthusamy, MD, MAS**  
Director of Endoscopy, UCLA Health System  
Professor of Clinical Medicine  
Vatche and Tamar Manoukian Division of  
Digestive Diseases  
David Geffen School of Medicine at UCLA  
Los Angeles, California  
1: The History of Gastrointestinal  
Endoscopy

**Zaheer Nabi, MD, DNB**  
Consultant Gastroenterologist  
Asian Institute of Gastroenterology  
Hyderabad, India  
55: Infections of the Biliary Tract

**Andrew Nett, MD**  
Paul May and Frank Stein Interventional  
Endoscopy Center  
California Pacific Medical Center;  
Department of Medicine  
University of California San Francisco  
San Francisco, California  
58: Pancreatic Fluid Collections and Leaks

**Nam Q. Nguyen, MBBS (Hons), FRACP,  
PhD**  
Associate Professor  
Head, Education and Research  
Department of Gastroenterology and  
Hepatology  
Royal Adelaide Hospital  
University of Adelaide  
Adelaide, South Australia, Australia  
8: Patient Preparation and  
Pharmacotherapeutic Considerations

**Nicholas Nickl, MD**  
Professor of Medicine  
University of Kentucky Medical Center  
Lexington, Kentucky  
31: Subepithelial Tumors of the Esophagus  
and Stomach

**Satoru Nonaka, MD, PhD**  
Endoscopy Division  
National Cancer Center Hospital  
Tokyo, Japan  
32: Diagnosis and Treatment of Superficial  
Gastric Neoplasms

**Ichiro Oda, MD**  
Endoscopy Division  
National Cancer Center Hospital  
Tokyo, Japan  
32: Diagnosis and Treatment of Superficial  
Gastric Neoplasms

**Robert D. Odze, MD, FRCPC**  
Professor of Pathology  
Department of Pathology  
Brigham and Women's Hospital  
Boston, Massachusetts  
5: Tissue Sampling, Specimen Handling, and  
Laboratory Processing

**Edward C. Oldfield IV, MD**  
Department of Internal Medicine  
Eastern Virginia Medical School  
Norfolk, Virginia  
9: Bowel Preparation for Colonoscopy

**Parth J. Parekh, MD**  
Department of Internal Medicine  
Division of Gastroenterology and  
Hepatology  
Tulane University  
New Orleans, Louisiana  
9: Bowel Preparation for Colonoscopy

**Patrick R. Pfau, MD**  
Professor of Medicine, Chief of Clinical  
Gastroenterology  
Division of Gastroenterology and  
Hepatology  
University of Wisconsin School of Medicine  
and Public Health  
Madison, Wisconsin  
22: Ingested Foreign Objects and Food Bolus  
Impactions

**Mathieu Pioche, MD, PhD**

# PREFACE

Welcome to the third edition of *Clinical Gastrointestinal Endoscopy*. Gastrointestinal endoscopy is a continuously evolving field with the advent of new technologies, refined techniques, and new applications. The prior editions of this book have been universally regarded as a comprehensive guide to the latest endoscopic techniques. Understanding and adoption of such practices leads to optimal outcomes with endoscopy. This text is unique because of the breadth of topics covered by experts in every discipline of gastrointestinal endoscopy from across the globe. *Clinical Gastrointestinal Endoscopy* has been an essential resource for anyone interested in learning about endoscopic procedures, as one can access a variety of topics in succinct, easily understood chapters from content specialists.

This edition marks the transition to a new editorial team and builds on the success of the two prior editions. The previous editions achieved great accolade due to the efforts of the editorial board lead by Gregory Ginsberg and coedited by Michael Kochman, Ian Norton, and Christopher Gostout. The new editorial team was selected due to their expertise in gastrointestinal endoscopy, enthusiasm for disseminating best practices to a worldwide audience, and diverse background of training and experience from different premiere institutions. Commensurate with the change in the editors, we were excited to invite a new set of content experts who share their insights into recent advances in endoscopy and the impact these innovations have had on improving patient care. This has led to an exciting, comprehensive textbook from today's most prestigious specialists.

*Clinical Gastrointestinal Endoscopy*, third edition, is divided into three main sections covering Equipment and General Principles of Endoscopy, Luminal Gastrointestinal Disorders,

and Pancreaticobiliary Disorders. Section I elegantly describes the history of gastrointestinal endoscopy and then provides primers on how endoscopes, endoscopic devices, and endoscopy units function. There are many applicable practice-changing pearls of wisdom in this section. Section II: Luminal Gastrointestinal Disorders covers both benign and malignant disorders as well as emerging endoscopic areas. Section III: Pancreaticobiliary Disorders details standard and advanced techniques in ERCP and EUS for the diagnosis and management of benign and malignant disorders of the pancreaticobiliary systems.

Each chapter has been meticulously crafted to present relevant updates to the topic in a manner that is easy to read and readily retained. These chapters are filled with tips that will help deliver optimal care for your patients. In addition, the content has been enhanced with new images and illustrations to highlight recent major advances in endoscopic techniques and applications for the latest technologies. These images and pictures can be downloaded from the book's website so that you can use them in your presentations. Furthermore, most topics have accompanying videos demonstrating the diagnostic and therapeutic endoscopic procedures. This media platform allows the reader to experience endoscopic procedures firsthand when accessing the content from their handheld device or computer. Each video clip has been meticulously edited to maximize the educational value.

The authors and editors draw upon their collective experience to provide you with the most current, authoritative, and impactful content for the sole purpose of enhancing the education of gastrointestinal endoscopy for years to come.

Vinay Chandrasekhara, MD

# DEDICATION

To my parents Bina and Kota and my sister Sheila, who provided a nurturing environment and encouraged me to dream big. The values that you instilled from an early age will forever remain with me.

To my wife Meghana and our children Siddhant and Adya, who have allowed me to pursue my dreams even if it meant being away from home. Every professional accomplishment is only possible because of your love and support.

To my colleagues, friends, trainees, and professional acquaintances: I appreciate everything you have taught me over the years. I am especially ever grateful to Drs. Gregory Ginsberg and Michael Kochman for providing me with unbelievable opportunities, including serving as an editor for this textbook.

—Vinay Chandrasekhara

To my parents, Carol and Hadi, for showing me the right path and to my wife, Alli, for taking it with me. To our patients, without whom there would be no progress.

—B. Joseph Elmunzer

This book is dedicated to my family, trainees, nurses, colleagues and mentors. It took a tremendous effort and commitment to put this comprehensive endoscopy book together. I am grateful to both my personal family and my work family who allowed me to have the focus, dedication, and time to be a coeditor of this book.

—Mouen A. Khashab

I dedicate this book to my teachers, colleagues, and trainees who continue to challenge me to question what is felt to already be known. To my patients for their inspiration in motivating me to continually improve on the care we deliver. To my entire family, I thank you for your constant love and support. Specifically, to my mother, who has always encouraged me to follow my own path, and to my father, who left a medical school faculty position in India 45 years ago to start over as a resident in the USA with nothing other than \$20 in his pocket and the American Dream, for the many opportunities I have had in my life and to whom I owe everything. Finally, to my wife Nanda and daughter Sonali for your substantial patience, compassion, warmth, and most importantly for bringing so much joy and laughter into my life.

—V. Raman Muthusamy

## SECTION I Equipment and General Principles of Endoscopy

### 3 How Endoscopes Work

Video 3.1 Distinguishing Colonic Pathology

### 11 Small-Caliber Endoscopy

Video 11.1 Transnasal Endoscopy

## SECTION II Luminal Gastrointestinal Disorders

### 14 Nonvariceal Upper Gastrointestinal Bleeding

Video 14.1 Endoscopic Clipping of Actively Bleeding Peptic Ulcer

### 15 Portal Hypertensive Bleeding

Video 15.1 Endoscopic Band Ligation

### 16 Lower Gastrointestinal Bleeding

Video 16.1 Contact Thermal Therapy for a Colonic Arteriovenous Malformation

Video 16.2 Combination Therapy for Delayed Postpolypectomy Bleeding I

Video 16.3 Combination Therapy for Delayed Postpolypectomy Bleeding II

### 17 Middle Gastrointestinal Bleeding

Video 17.1 VCE With Fresh Blood

Video 17.2 VCE With Suspected Celiac Disease

Video 17.3 VCE With Angiectasia

Video 17.4 VCE With Suspected Crohn's Disease (1)

Video 17.5 VCE With Suspected Crohn's Disease (2)

Video 17.6 VCE With Ulcerated Small Bowel Mass Lesion

Video 17.7 VCE With GIST

Video 17.8 VCE With Large Submucosal Mass Lesion

Video 17.9 VCE With NSAID Enteropathy (1)

Video 17.10 VCE With NSAID Enteropathy (2)

Video 17.11 Double-Balloon Enteroscopy With Ulcerated Jejunal GIST

Video 17.12 Double-Balloon Enteroscopy With Neal Hemangioma

Video 17.13 Double-Balloon Enteroscopy With Small Bowel Angiectasia

Video 17.14 Double-Balloon Enteroscopy With Metastatic Melanoma

Video 17.15 Double-Balloon Enteroscopy With Polypectomy in Peutz-Jehger's Disease

Video 17.16 Double-Balloon Enteroscopy With Balloon Dilatation of Crohn's Stricture

Video 17.17 Spiral Enteroscopy

### 19 Esophageal Motility Disorders

Video 19.1 Peroral Endoscopic Myotomy in Achalasia (1)

Video 19.2 Peroral Endoscopic Myotomy in Achalasia (2)

Video 19.3 Peroral Endoscopic Myotomy in Achalasia (3)

Video 19.4 Peroral Endoscopic Myotomy in Achalasia (4)

### 20 Endoscopic Diagnosis and Management of Zenker's Diverticula

Video 20.1 Endoscopic Management of Zenker's Diverticulum

### 23 Eosinophilic Esophagitis

Video 23.1 Esophagitis

Video 23.2 Fixed Rings and Stenoses Characteristic of EoE

Video 23.3 Salient Endoscopic Features of EoE

### 24 Gastroesophageal Reflux Disease

Video 24.1 Endoscopic Evaluation of a Surgical Nissen Fundoplication

### 25 Barrett's Esophagus: Diagnosis, Surveillance, and Medical Management

Video 25.1 Barrett's Esophagus Inspection Technique

### 26 Screening for Esophageal Squamous Cell Carcinoma

Video 26.1 Esophageal Squamous Cell Carcinoma With Verdacious Features

Video 26.2 Long Segment Esophageal Squamous Cell Carcinoma In Situ

### 27 Endoscopic Treatment of Early Esophageal Neoplasia

Video 27.1 Cap-Assisted Endoscopic Mucosal Resection

Video 27.2 Band Endoscopic Mucosal Resection

### 29 Endoscopic Approaches for Gastroparesis

Video 29.1 Gastric Peroral Endoscopic Pyloromyotomy

### 31 Subepithelial Tumors of the Esophagus and Stomach

Video 31.1 Endoscopic Ultrasonography of Subepithelial Lesion: Gastrointestinal Stromal Tumor

Video 31.2 Endoscopic Ultrasonography of Submucosal Lesion: Lipoma

Video 31.3 Endoscopic Ultrasonography of Extramural Lesion: Hepatic Hemangioma

### 32 Diagnosis and Treatment of Superficial Gastric Neoplasms

Video 32.1 Systematic Examination of Endoscopic Images

Video 32.2 Endoscopic Submucosal Dissection Using IT Knife for Early Gastric Cancer—Greater Curvature of Lower Gastric Body

Video 32.3 Endoscopic Submucosal Dissection Using IT Knife for Early Gastric Cancer—Lesser Curvature of the Lower Gastric Body

### 33 Palliation of Gastric Outlet Obstruction

Video 33.1 Self-Expandable Metal Stent Placement for Malignant Gastric Outlet Obstruction

### 34 Duodenal and Papillary Adenomas

Video 34.1 Endoscopic Mucosal Resection of a Duodenal Adenoma

Video 34.2 En-Bloc Papillectomy

Video 34.3 Endoscopic Resection of a Lateral Spreading Lesion of the Papilla

### 37 Colonoscopic Polypectomy, Mucosal Resection, and Submucosal Dissection

## INTRODUCTION

The role of the physician is to observe, detect anatomic abnormalities or disease, and conceive ways and means by which discovered deficiencies in function can be corrected or ameliorated. To extend the physical examination to areas hidden from external view, such as within body orifices, presents a problem of safe and effective access. In insatiable attempts to accomplish these goals, there is no human orifice along with its recesses that has not been inspected, probed, prodded, and otherwise examined over the centuries. It was a compelling necessity to develop safe, nonsurgical methods to accomplish this purpose. Before the 20th century, numerous attempts to access these hidden cavities were plagued by instrumentation that was inadequate and dangerous. The history of every science or technical development is invariably a series of small discoveries or innovations, often in fields remote from those under investigation. Small improvements, each resulting in incremental gains, lead toward the idealized goal. Often, changes that appear to be an advance are found to be an impediment by further discoveries, and we recognize that a different way is better. Therefore, the task is never ending.

The term *endoscopy* comes from the Greek prefix *endo-* ("within") and the verb *skopein* ("to view or observe"). In this chapter, we summarize major developments over the years in gastrointestinal (GI) endoscopy to the present. As in any summary, the contributions of some individuals inevitably are not cited, and we offer our apologies to these individuals.

## SEQUENTIAL HISTORY OF ENDOSCOPY

The visual exploration and examination of body orifices date to at least Egyptian and later Greco-Roman times, during which

mechanical specula for viewing the vagina and anus were developed and used to a limited extent. Further progress was delayed by lack of sufficiently strong metals and the ability to form them into usable instruments, as well as the lack of adequate illumination. These initial efforts were directed at the genitourinary (GU) tract, with cavities that were only a short and relatively straight distance from the exterior.

Bozini (1805) is credited with the earliest known attempt to visualize the interior of a body cavity with a primitive endoscope (Fig. 1.1).<sup>1–4</sup> Bozini devised a tin tube illuminated by a candle from which light was reflected by a mirror; this was a device he called a *lichtleiter* (light conductor). He used this device to examine the urethra, urinary bladder, and vagina, but it was an impractical instrument that never gained wide acceptance. Although there were multiple attempts to develop more usable instruments, all directed toward the GU tract, none were widely used. The most notable efforts were by Segalas in France in 1826 and Fisher in Boston in 1827,<sup>5</sup> both using straight metal tubes, but the lack of a satisfactory light source remained a major impediment.

The next significant development was the instrument of Desormeaux in France.<sup>6</sup> Desormeaux's contribution in 1855 was a better, although still inadequate, light source using a lamp fueled with alcohol and turpentine ("gazogene") (Fig. 1.2). His instrument was based on that of Segalas. Others continued with efforts to improve the light source and the means to deliver it, but the devices were unsatisfactory for the more inaccessible areas of the GI tract.

### Rigid Gastrointestinal Endoscopes

Kussmaul is credited as being the first to perform a gastroscopy in 1868, using a straight rigid metal tube passed over a flexible obturator and a cooperative sword swallower (Fig. 1.3).<sup>1–4</sup> For a light source, he used a mirror reflecting light from the

### Abstract

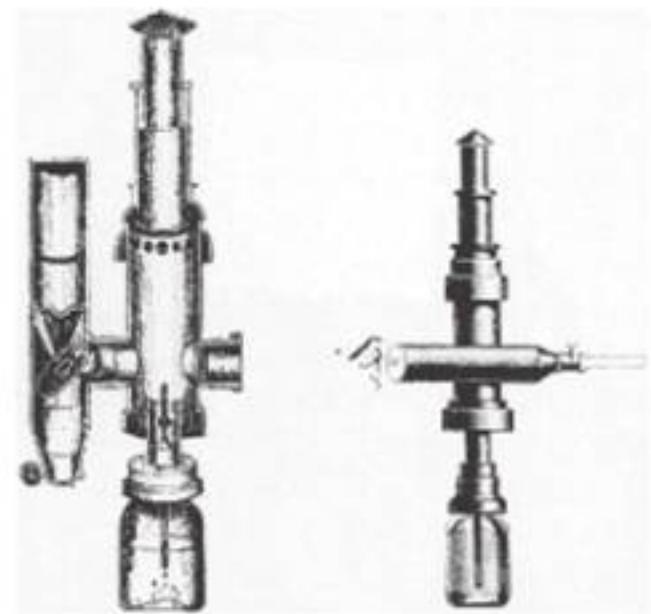

The development of endoscopy is a testimony to human ingenuity. Instruments have evolved from dangerous straight tubes, illuminated by light reflected from candles, to more flexible and safer instruments with an image transmitted through a series of prism lenses and illumination by an electric light bulb, to images transmitted through fiberoptic bundles with illumination transmitted by fiber bundles from an external source, to our present remarkably safe electronic instruments with digital images transmitted to a video screen through wires and processed by computers. Most recently, we can visualize the lumen of the gut without touching the patient. Now we not only can visualize, biopsy tissue, and perform procedures within the hidden cavities of the body, but also directly and indirectly see beneath the mucosa and into immediately adjacent organs. The evolution of gastrointestinal endoscopy is a truly remarkable story, and advances in the diagnostic and therapeutic capabilities of these instruments continue to be made at a rapid pace. To know and understand what has occurred previously lends strength to efforts toward achieving what is to come.

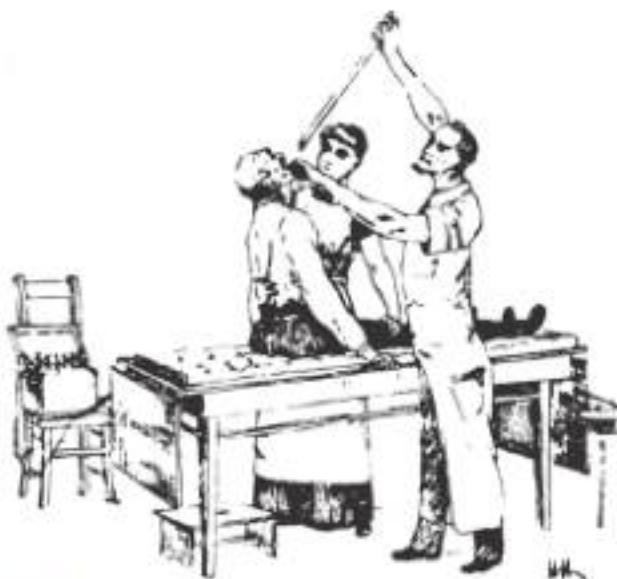

**FIG 1.1** Bozzini's lichtleiter, 1805. (From Edmonson JM: History of the instruments for gastrointestinal endoscopy. *Gastrointest Endosc* 37[Suppl 2]:S27–S56, 1991.)

**FIG 1.2** Desormeaux's endoscope, 1853. (From Edmonson JM: History of the instruments for gastrointestinal endoscopy. *Gastrointest Endosc* 37[Suppl 2]:S27–S56, 1991.)

Desormeaux device but found it inadequate. He also quickly discovered that gastric secretions were a problem, despite using a flexible tube he had developed earlier to empty the stomach before the procedure. The value of his efforts was the demonstration that the curves and bends of the esophagus and esophago-

**FIG 1.3** Kussmaul's gastroscope, 1868. (From Edmonson JM: History of the instruments for gastrointestinal endoscopy. *Gastrointest Endosc* 37[Suppl 2]:S27–S56, 1991.)

gastric junction could be traversed with careful manipulation and that the gastric pouch could be visualized. Kussmaul apparently demonstrated his "gastroscope" several times, but the illumination was too poor to allow a clinically useful image,<sup>4</sup> and he abandoned his efforts.

Encouraged by the efforts of Kussmaul, others switched their attention to developing esophagoscopes because the esophagus is much easier to visualize, and a less complex design than the gastroscope was required. The problems of perforation, at that time usually fatal, and of illumination, remained major obstacles. Before the late 19th century, illumination of light reflected by a mirror into a straight metal tube continued to be used. As noted earlier, several light sources were developed, but the intensity left much to be desired. Several innovations were developed to solve this problem, including a burning magnesium wire, which produced a brilliant light but unacceptable heat and smoke. The most promising device seemed to be the brilliant light from a loop of platinum wire charged with direct current, introduced simultaneously by Brück in Breslau and Milliot of Paris in 1882.<sup>5</sup> Although the illumination was adequate, major difficulties were encountered with the considerable heat generated, necessitating a water cooling system and the cumbersome batteries used for a power source. Nevertheless, the platinum wire device was an encouraging development and was used in several instruments that saw relatively widespread use.

These instruments were made obsolete just a few years later by Edison's incandescent electric light bulb, introduced in 1879. In 1886, Leiter, an instrument maker, was the first to use the electric incandescent light bulb in a cystoscope just 7 years after Edison introduced it. With a few short-lived exceptions, all instruments used Edison's invention after 1886. Working with Leiter, von Mikulicz developed an unsuccessful gastroscope but a practical esophagoscope that he used extensively until distracted by his many other medical interests.

At the turn of the 20th century, Jackson, an otolaryngologist, also examined the esophagus and the stomach using a straight rigid tube and a distal electric light bulb, but few could match

his talents in the GI tract. Under his influence, esophagoscopy was considered the exclusive province of ear, nose, and throat (ENT) departments in many community hospitals in the United States as late as the 1950s. The design of the esophagoscope remained a straight rigid tube, usually with a rubber finger-tipped obturator to make insertion safer. With the later addition of a 4 × power lens on the proximal end and a distal incandescent bulb, various models were popular until the introduction of fiber optics in 1961. The Eder-Hufford rigid esophagoscope (Fig. 1.4), introduced in 1949, was popular and still in use in the early 1960s.

It was not until after 1900 that persistent efforts to develop a usable gastroscope were successful. All attempts to build a flexible instrument using a multiplicity of lenses were designed to be straightened after introduction and were fragile, easily damaged, and cumbersome. Straight tubes with simpler optics were useful, but perforations were still a problem.<sup>1</sup> In 1911, Elsner introduced a rigid gastroscope with an outer tube through which a separate inner optical tube with a flexible rubber tip and side-viewing portal could be passed (Fig. 1.5). The rubber tip, previously used in the esophagoscope obturator, was more crucial than it might appear, for it seemed to be, along with the later

addition of a flexible metal coil proximal to it, the single feature that reduced the rate of perforation. Elsner's instrument worked as designed and was widely used, especially by Schindler, then in his native Germany, who called it the "mother of all instruments until 1932."<sup>3</sup>

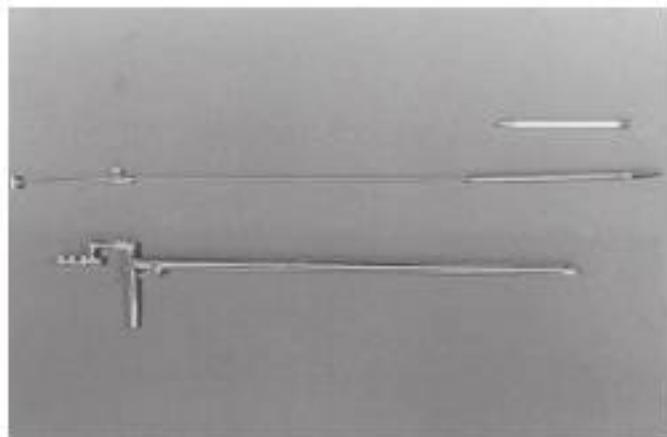

In 1922, Schindler introduced his own version of the Elsner gastroscope, the major innovation of which was the important addition of an air channel to clear the lens of secretions. With the Elsner gastroscope, Schindler examined the stomachs of several hundred patients and meticulously recorded his findings in each procedure. He published *Lehrbuch und Atlas der Gastroskopie* in 1923, with descriptions and remarkably accurate drawings. He trained others in the technique and was responsible for wide acceptance of gastroscopy. The procedure began with emptying the stomach using a nasogastric tube, followed by sedation. The patient was placed on the left side, and an assistant held the head rigidly extended to produce a straight path into the esophagus and the stomach (the "sword swallower's technique"). The role of the assistant was crucial. Schindler's effort was impressive and convinced many of the value of an expert examination of the stomach.

### Semiflexible Gastrosopes

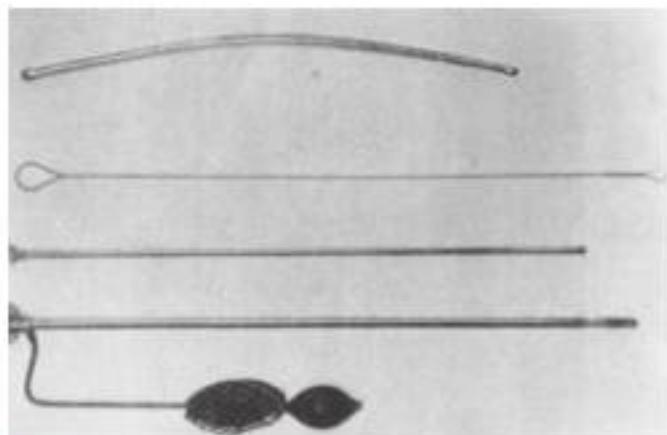

It became apparent that straight, rigid tubes were not ideal for examination of the stomach. Fatal perforations continued to the detriment of acceptance of the procedure. Visualization of the surface of the stomach was incomplete at best, with many consistent blind spots. These problems stimulated investigation of methods to manufacture safer, "flexible" instruments. The use of the term *flexible* here is problematic in view of what we think of today as flexible instruments. Although these early instruments were not flexible by our standards, they were more flexible than the straight, rigid instruments that came before. *Semiflexible*, with passive angulation of the distal portion of 34 degrees and sometimes more, was a more appropriate term.

In 1911, Hoffman showed that an image could be transmitted through a curved line by linking several short-focus prisms. Using this principle, several instruments were constructed, but these were unsatisfactory or were not widely accepted. Schindler, working with Wolf, the renowned instrument maker, constructed a semiflexible instrument with a rigid proximal portion and a distal portion made elastic by coiled copper wire and terminating with first a rubber finger and later a small rubber ball. Illumination was with a distal incandescent light bulb. Air insufflation was made possible with a rubber bulb, expanding the stomach wall to beyond the focal length of the prisms, which were manufactured by Zeiss. In 1932, the sixth and final version was patented. This instrument, known as the Wolf-Schindler gastroscope, greatly improved the safety and efficacy of gastroscopy and was used throughout the world (Fig. 1.6).

Thanks to the published meticulous work and enthusiasm of Schindler, whose designation as the "father of gastroscopy" is well deserved, the procedure was finally widely accepted as a valuable extension of the physical examination. The era of the semiflexible gastroscope from 1932 to 1957 has been called the *Schindler era*. Schindler was chiefly responsible for transforming gastroscopy from a dangerous and seldom used procedure to one that was relatively safe and indispensable for evaluation of known or suspected disease of the stomach. He insisted that all clinicians who planned to use the instrument be properly trained and that "... no manipulation inside of the body is without danger; therefore no endoscopic examination should be done

**FIG 1.4** Eder-Hufford esophagoscope, the result of multiple attempts to develop a clinically useful instrument, 1949.

**FIG 1.5** Elsner's gastroscope, 1911. (From Edmonson JM: History of the instruments for gastrointestinal endoscopy. *Gastrointest Endosc* 37[Suppl 2]:S27–S56, 1991.)

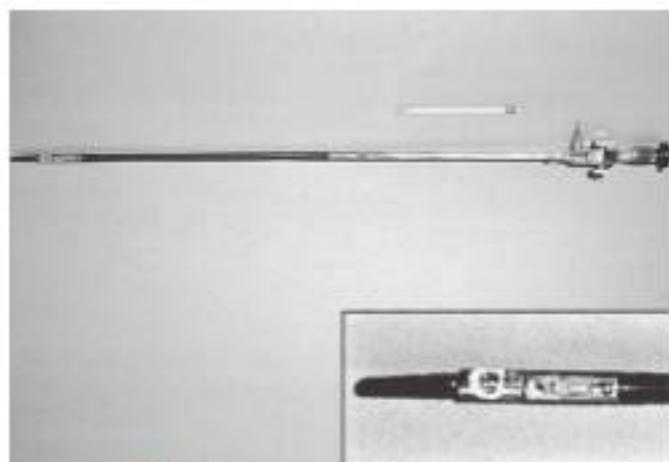

**FIG 1.6** Wolf-Schindler "flexible" gastroscope (top) being used by Schindler (bottom) with his wife as the head holder. (From Edmonson JM: History of the instruments for gastrointestinal endoscopy. *Gastrointest Endosc* 37[Suppl 2]:S27–S56, 1991.)

without reasonable indication.<sup>16</sup> In today's vernacular, the risk approaches infinity if the benefit approaches zero.

Schindler was born in Berlin in 1888. He gained considerable experience as an Army physician in World War I, where he became convinced that gastritis, then an often-disparaged cause of symptoms, was a bona fide disease. His interest in gastritis lasted throughout his career and undoubtedly stimulated his interest in gastroscopy. The Wolf-Schindler endoscope of 1932 and Schindler's publications with drawings further enhanced what thereafter rapidly became a discipline. His enthusiasm for and talent in using the gastroscope led to what has been called his *gospel of gastroscopy*, which he and others spread throughout academia and to the community of practicing physicians. Because of his Jewish background, Schindler was put in "protective custody" by the Nazis, but with the help of the physicians Ortmeyer and Palmer and philanthropists in Chicago, he was able to immigrate to the United States in 1934.<sup>1–4,7</sup>

Chicago became the hub of GI endoscopy, and it was here, in Schindler's home, that the first discussions were held about forming a new organization for GI endoscopy, now known, after several name changes, as the *American Society of Gastrointestinal Endoscopy*. In 1943, just 9 years after his arrival in the United States, Schindler left Chicago for Loma Linda University. In 1958, he accepted an appointment as Professor of Medicine at the

**FIG 1.7** Benedict operating gastroscope.

University of Minas Gerais in Belo Horizonte, Brazil. He came back to the United States in 1960 because of an eventually fatal illness of his wife and returned to his native Berlin in 1964, where he died in 1968 at the age of 80.<sup>1</sup> Despite his acclaim in endoscopy, Schindler insisted that one must be a physician first and an endoscopist second. He was very knowledgeable in the field of general gastroenterology and published, without coauthors, a synopsis of the entire field in 1957.<sup>1</sup>

The Wolf-Schindler endoscope was introduced into the United States by Benedict, Borland, and many others. Schindler's immigration to Chicago inspired a surge of interest in the United States, but with the outbreak of war in Europe, the German source of instruments disappeared. Several US companies working with Schindler and others produced many popular gastrosopes that were significant variations on the Wolf-Schindler model, including Cameron Co., which produced its first instrument in 1940.<sup>1</sup> The Eder-Hufford semiflexible gastroscope followed in 1946,<sup>2</sup> and American Cystoscope Makers, Inc. (ACMI) produced a gastroscope in 1950. A combination of the Eder-Hufford esophagoscope with a semiflexible gastroscope to be passed through it was the Eder-Palmer transesophageal flexible gastroscope produced by the Eder Company in 1953. Each gastroscope had its proponents.

### Biopsy

With the availability of instruments for visualization, it became apparent that tissue must be obtained to identify the nature of the observed abnormalities. Instruments for blind biopsies were used early on, but a device was needed that would allow the operator to obtain a biopsy specimen of abnormal tissue directly when seen at endoscopy. The Benedict Operating Gastroscope was produced in 1948 based on a 1940 model by Kenamore (Fig. 1.7).<sup>10</sup> The Benedict instrument was a popular instrument that was widely used. In the debates about the necessity for biopsy, Benedict, a surgeon who switched entirely to endoscopy, stated that gastroscopy was not a routine procedure and should be reserved for those with a complex differential diagnosis, but "gastroscopic examination is not complete unless the gastroscopist has some means of biopsy readily available."<sup>11</sup> It soon became clear that the correlation between histology and a diagnosis based on visualization alone was often widely discrepant, and certain diagnoses could not be reliably made without tissue examination.

Efforts such as wash and brush cytology continued and have persisted in various forms to the present time.

### Fiberoptics

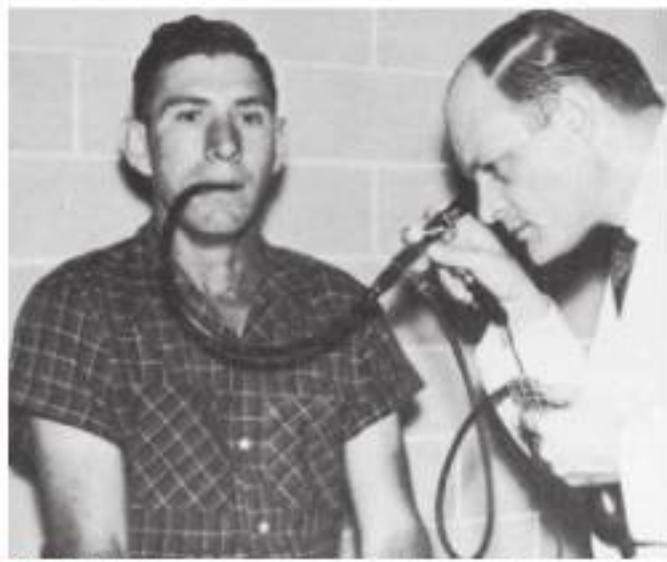

By the 1950s, the ideal of a totally flexible GI endoscope with good visualization that could withstand the rigors of clinical use had not been realized, although the semi-flexible instruments with their biopsy capabilities were satisfactory for most clinical purposes. In fact, these instruments were not rapidly abandoned by all with the introduction of the remarkably flexible fiberscope. The development of the science of fiberoptics and its application to endoscopes truly revolutionized the diagnostic and, later, the therapeutic abilities of endoscopy. Its importance in the development of this field cannot be overstated.

The principle of internal reflection of light along a conduction pathway was used by Lamm in October 1930.<sup>1</sup> The image was severely degraded by light escaping from the thin fibers of quartz he used, although the potential for total flexibility was present. Lamm could not interest Schindler or others in his efforts, and the experiment was discontinued. Almost 25 years later, in 1954, Hirschowitz, in fellowship training at the University of Michigan, visited Hopkins and Kapany in London to review their work<sup>12</sup> with glass fibers, which totally confirmed the work of Lamm and his predecessors. Hirschowitz became convinced that application of this principle could be used to develop a totally new and superior endoscope. He began work with a graduate student, Curtiss, who developed a technique of coating glass fibers with glass of a different optical density, preventing the escape of light and degradation of the image. This was the critical discovery that made the principle of internal reflection through glass fibers workable.

In 1957, Hirschowitz demonstrated his fiberscope, and he published his work in 1958 (Fig. 1.8).<sup>13</sup> His audience was not impressed, and it took another 3 years, working with ACMI, to produce a marketable scope, which he called the *Hirschowitz*

*Gastroduodenal Fiberscope*. This was a very flexible side-viewing instrument with an electric light on its distal end, an air channel, and an adjustable focusing lens proximally. The tip lacked what was by then the "obligatory" rubber finger, and this omission was a source of criticism; one was added on a later model. Although some individuals criticized the quality of the image, most believed the size and brightness were superior to the semiflexible scopes. This model, the ACMI 4990, was introduced to the market late in 1960 after being tested by Hirschowitz on himself and numerous patients. In 1961, the senior author of this chapter was in a gastroenterology fellowship at the Emory University Clinic with Schroder. He vividly recalls Schroder's reaction after the first use of the new fiberscope around March 1962 (Fig. 1.9). Upon finishing the initial examination using the new device, he turned to him and said, "Anybody want to buy a used Benedict operating scope?" The senior author does not recall it ever being used again, as the Hirschowitz Gastroduodenal Fiberscope was clearly superior in his view, and he finished his training with that instrument.

There were problems with the fiberscope noted by users. The distal light source would become so heated that thermal injury to the gastric mucosa was possible unless the tip was continuously moved. In prolonged procedures, protein in gastric secretions would coagulate on the bulb and the adjacent visualizing port, totally obscuring the lens. As the number of procedures with a single instrument increased, some glass fibers would break, producing small black dots in the visual field. This was a persistent problem with fiberscopes during their entire history and especially apparent in training programs where a single scope was used by several trainees on many patients. The side-viewing lens prevented visualization of the esophagus, and the scope had to be passed blindly through the pharyngeal orifice. The previous semiflexible scopes in use shared this problem, and it was not considered a defect at the time. The flexibility itself resulted in some difficulty in advancing because attempts to push the instrument through the pylorus and into the gut resulted in more bowing in the gastric pouch (Fig. 1.10). Although one could sometimes visualize the duodenum, this was done by overinflating the stomach and looking through the pylorus without actually entering it. If one managed to introduce the tip into the duodenum, as occasionally happened, the visual field was inside the focal length of the instrument, and only a "red-out" was observed.<sup>4</sup>

**FIG 1.8** Hirschowitz examining the stomach of an outpatient. (From Hirschowitz BI. Endoscopic examination of the stomach and duodenal cap with the fiberscope. *Lancet* 277[7186]:1074–1078, 1961.)

**FIG 1.9** ACMI fiberscope, 1962.

**FIG 1.10** Visualization of duodenum was sometimes obtained by overinflating the stomach.

Many clinicians did not believe the additional expense of replacing the older, beloved instruments with which they had been successful for many years was warranted. Even ACMI officials did not see the fiberscope as totally replacing the instruments with a lens system.<sup>2</sup> Despite reservations, comparison and experiential studies showed the advantages of the new fiberscopes.<sup>14–17</sup> Following the flagship ACMI model 4990, several models of the fiberscope were introduced by ACMI and other companies, each with significant improvements, including the controllable tip in the side-viewing ACMI model 5004. Visualization of the gastric pouch, including retroflexed views of the cardia, was now complete. The major objection to these instruments was the inability to pass the instrument under direct vision and examine the esophagus; in addition, the area beyond the pylorus could not be consistently examined.

Most clinicians were already fully trained in use of the Eder-Hufford esophagoscope, and in the absence of a forward-viewing fiberscope, use of the Eder-Hufford esophagoscope continued. A forward-viewing scope was mandatory. LoPresti modified the tip of the fiberscope to create the foroblique fiberoptic esophagoscope in 1964.<sup>18</sup> Passing the instrument under direct vision was possible, and clinicians immediately discovered that they could examine not only the esophagus, but also a large portion of the proximal stomach. At a length of 90 cm, however, one could not reach the duodenum. Working with ACMI, LoPresti produced the longer Panview Mark "87" gastroesophageal endoscope in 1970. By about 1971, the instrument had been lengthened to 105 cm with a four-way controllable tip capable of 180 degrees of deflection (Fig. 1.11).

**FIG 1.11** LoPresti forward-viewing esophagogastroscope. (From advertisement in *Gastrointest Endosc* 16:79, 1970.)

The aptly named *panendoscope* was now a reality. Japanese and American manufacturers began to produce new models with such rapidity that endoscopists hardly had time to become thoroughly familiar with one before another, significantly improved (and more expensive) model was on the market. Patient comfort was greatly improved, and the relative safety of the fiberoptic endoscopes rapidly became apparent. By 1970, most gastroscopic examinations were done with fiberscopes. The development of a "teaching head" fiberoptic bundle with a light splitter and attached eyepiece and attachment to the eyepiece of the scope allowed two people to visualize the image. Dividing the light from the endoscope considerably diminished the brightness of the image, however, to both the operator and the observer. This device saw limited use and was utilized primarily in teaching institutions.

### Endoscopic Retrograde Cholangiopancreatography (ERCP)

With access to the duodenum, the ampulla of Vater became visible. It followed that one should be able to inject contrast material into the bile and pancreatic ducts and increase diagnostic capabilities. Initial attempts in 1968 by McCune et al<sup>19</sup> to modify an existing scope were only partially successful, but did show that endoscopic visualization by injection of radiologic contrast agents into ducts was possible. In 1970, Machida and Olympus in Japan produced usable, side-viewing scopes with controllable tips and elevators to move the injection tube to the ampulla.

Japanese endoscopists<sup>20</sup> developed the technique of endoscopic retrograde cholangiopancreatography (ERCP) with an 80% success rate. Vennes and Silvis<sup>21</sup> showed the utility of ERCP in the United States and taught many physicians to use it.<sup>4</sup> It was immediately apparent that if clinicians could visualize the biliary and pancreatic ducts endoscopically (i.e., nonsurgically), they should be able to apply by some means long-established surgical techniques for treatment of choledocholithiasis and pancreatitis, such as sphincterotomy and stone removal. In 1974, just 4 years after the demonstration of the diagnostic utility of the new ERCP

scopes, Kawai et al in Japan<sup>21</sup> and Classen and Demling in Germany<sup>22</sup> independently developed methods of endoscopic electrosurgical sphincterotomy for extraction of biliary calculi in the common duct. This procedure requires great skill; in 1976, Geenen<sup>24</sup> reported that only 62 operative procedures had been done by four endoscopists, and seven of the procedures were failures. In 1983, Schuman<sup>4</sup> reported that several thousands of patients had undergone ERCP, and by now, hundreds of thousands of ERCP procedures have been done. Because of advances in radiologic techniques, ERCP is now seldom used for purely diagnostic purposes.

### Photography

It is one thing to describe to others what one may see through any device and another to be able to show them. The large impact of Schindler's early publications was related, in part, to the excellent color drawings he presented. Early on, neither cameras nor photographic films were advanced enough to allow good color reproduction or sharp, accurate images in relatively poor lighting. Such documentation is essential for widespread appreciation of endoscopy by individuals who do not perform the procedure. The first clinically useful photography came with improvements in film by Kodak and the construction of an external integrated camera by Segal and Watson in 1948.<sup>25,26</sup> Although these authors reported that approximately 61% of the images were of good quality, this was not the experience of all clinicians.<sup>4</sup>

Although an intragastric camera was developed as early as 1848 by Lange and Meltzung, a clinically useful device was not available until 1950, when Uji, Sugiura, and Fukami, working with Olympus Corp. (Center Valley, PA),<sup>27</sup> developed the Gastrocamera with synchronized flash, which took good intragastric pictures and had a controllable distal portion. By following a prescribed pattern of rotation and flexion, a series of pictures was obtained that included the entire surface of the stomach. The big disadvantage was that the operator could not see through the instrument and had to await development of the very narrow (5-mm) film before the results could be seen. Photographs for demonstration required additional time in the photo laboratory while enlargements were made.

After the introduction of fiberoptic scopes in 1961, Olympus introduced a combination Gastrocamera fiberscope (GTF-A) in 1964, but, as Schuman<sup>4</sup> commented, "it was just a gastroscope" and never attained popularity. Simultaneously, rapid development and physician acceptance of fiberscopes with the ability to use technically advanced 35-mm cameras with an external adapter made the Gastrocamera obsolete, and it was abandoned.

### Sigmoidoscopy and Colonoscopy

The problems presented by examination of the anus and rectum were relatively easy. Straight metal tubes were used and found in the ruins of Pompeii.<sup>2</sup> The basic design of the anoscope has not changed in the past century or more except that it is now made of disposable plastic. It remains a tapering short tube with an obturator that is removed after introduction through the anal sphincter. Examination of the rectum and sigmoid required a longer tube, but no truly satisfactory device was available until 1894, when Kelly<sup>28</sup> at Johns Hopkins developed a 30-cm rigid tube with light reflected down the tube from a head lamp. Tuttle<sup>29</sup> incorporated a distal light source in his proctosigmoidoscope of 25 cm in 1903. These instruments have remained the basic design for the past 100 years. For the past 25 years or so, disposable

clear plastic tubes have been widely used. These are essentially a plastic version of the Kelly and Tuttle tubes with a distal electric light source, but visualization is possible through the clear plastic. With the application of fiber optics to sigmoidoscopy in the late 1960s, examination of the sigmoid colon became not only satisfactory, but also much more comfortable for the patient.

Overholt,<sup>30</sup> who later went on to be the principal developer of colonoscopy using similar technology, presented his results of flexible sigmoidoscopy in 250 patients in 1968. Although early flexible sigmoidoscopes were made in variable lengths, the current length of 60 cm came to be the preferred one. Examination of the colon above the sigmoid presents obvious additional problems of multiple curves and angulations amenable only to highly flexible instruments and trained operators. Attempts, all unsuccessful, were made using semiflexible instruments, and these are reviewed by Edmonson.<sup>2</sup> Satisfactory examination of the length of the colon was impossible until the introduction of the flexible fiberoptic. Attempts to use forward-viewing gastrosopes were not technically satisfactory, although several clinicians tried. Turell<sup>31</sup> presented his attempts in 1967 using a modified gastroscope, but he concluded that the instrument was not ready for routine clinical use. By 1970, several manufacturers produced instruments specifically designed for colonoscopy, including ACMI working with Overholt in the United States and Olympus Corporation in Japan.

The primary problem with regularly completing examinations to the cecum was not the instruments so much as it was the techniques necessary for passage of the scopes into the more proximal portions of the colon. Earlier pioneers in developing successful techniques still in use include, among others, Overholt, Wolf, Shinya, and Waye in the United States; Niwa and colleagues in Japan; Salmon and Williams in England; and Dehyle in Germany.<sup>4</sup> Many of these early efforts were accomplished with the guidance of fluoroscopy to negotiate the more difficult turns and to identify the actual area being observed, but, as experience was gained, fluoroscopy was no longer required. Learning under expert guidance and experience continues to be more necessary in colonoscopy (and ERCP) than in upper endoscopy. By 1971, the diagnostic advantage of fiberoptic colonoscopy over single-contrast barium enema was firmly established,<sup>32</sup> and the efficacy and safety of polypectomy were established by 1973.<sup>33</sup>

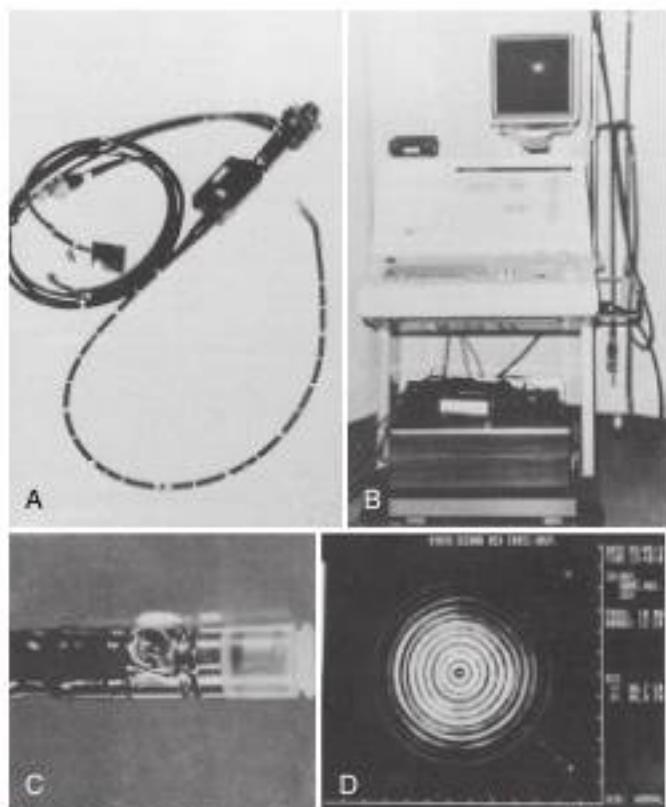

### Digital Endoscopy (Videoendoscopy)

In 1984, barely 20 years after introduction of the endoscopic fiberscope, Welch Allyn, Inc. (Skaneateles Falls, NY), replaced the coherent fiberoptic image bundle in a colonoscope with a light-sensitive computer chip or charge-coupled device on which the image was focused by a small lens (see Chapter 3).<sup>34</sup> The digital signal was fed to a video processor, which generated an image to a television monitor. The image did not occupy the entire screen, leaving space for information to be typed in by a keyboard. The resolution of the image was at least equal to that of the fiberscope.

It was unnecessary to change the basic mechanics of the fiberscope. The fiberoptic light bundle remained unchanged, as did water, suction, and biopsy channels; in addition, the deflection and locking mechanisms were the same. The basic elements of the videoendoscope have not changed, although a magnified image is now available. Since the original introduction of the videoendoscope by Welch Allyn, which no longer produces the Video Endoscope, the market has been supplied by Olympus, Pentax, and Fujinon. The technology was rapidly adapted to

**FIG 1.12** Fujinon fiberoptic panendoscope (top) and its successor, the Videopanendoscope (bottom), 1990, showing the two kinds of operating heads. (From advertisement in *Gastrointest Endosc* 36:240–241, 1990.)

**FIG 1.13** **A** to **D**, Ultrasonic endoscope system, model IV, made by Olympus Corp., 1986. (From Yasuda K, Mukai H, Fujimoto S, et al: The diagnosis of pancreatic cancer by endoscopic ultrasonography. *Gastrointest Endosc* 34:1–8, 1988.)

all endoscopes, used not only in gastroenterology but also in other fields.

Advantages of the electronic instruments include an image that can be seen not only by the operator, but also by anyone with access to a connected monitor in the same or another room. This feature greatly enhanced the ability to teach others about the procedure and to inform other interested physicians about the findings in the individual patient. If desired, recording of procedures could be accomplished with videotape machines, and good-quality pictures of individual frames could be made immediately with externally integrated digital equipment. Individual endoscopists found that no adjustment of techniques was necessary when videoendoscopes were used, although they had to become accustomed to looking at the monitor screen rather than through an optical system with one eye (Fig. 1.12). This feature added to the useful length of the instrument because the whole scope could be held at the waist rather than being brought to eye level.

More recent innovations in colonoscopy instruments by Olympus include the ability to make a portion less flexible to facilitate navigation of difficult bends and turns. In addition, an enlarged image is now available that is an improvement in vision and ease of manipulation. A major disadvantage of videoendoscopes is cost. Fiberoptic endoscopes, when they were still in use, could be purchased for less than \$6000 and did not require processors or monitors, whereas the latest videoendoscopes are priced at more than \$20,000, and initial purchase of the entire package of endoscope, processing computer, monitors, and attachments may exceed \$30,000. Initially, many questioned the wisdom of this added cost, which is passed on to the patient and their insurance companies.

### Endoscopic Ultrasonography (EUS)

Although the improvements in GI endoscopy are remarkable in the synthesis of diverse but complementary technologies, the information gained remains confined to what one can see from

within the lumen of the gut. Simultaneous with these developments were those of computed tomography and external ultrasonographic tomograms. Conceptually, it was not only logical but also compelling to look beneath the mucosa of the gut by incorporating miniaturized models of ultrasonographic transducers already in use into GI endoscopes. The ability to noninvasively explore tissue and organs in proximity to the gut had exciting implications for diagnosis and therapy.

In Germany in 1976, working with Siemens Co., (Berlin, Germany) Lutz and Rosch<sup>13</sup> reported the use of a 1-cm ultrasonographic 4-MHz probe that could be passed through the biopsy channel of an Olympus TGE. They used it in two patients to successfully differentiate between pancreatic pseudocysts and tumors.<sup>7</sup> In 1980, Classen's group in Germany<sup>14</sup> and DiMagno et al<sup>15</sup> at the Mayo Clinic reported EUS devices that were incorporated onto the tip of conventional fiberscopes, one using a 5-MHz transducer and the other using a 10-MHz transducer. These probes had good resolution at an acoustic focus depth of 3 cm. Others incorporated the transducer in the distal shaft of fiberoptic scopes and primarily explored the gut wall.<sup>13,16</sup> By 1985, ultrasonic transducers with variable frequencies incorporated into videoendoscopes were readily available, although expensive (> \$100,000 for initial setup) (Fig. 1.13). It was immediately apparent that this procedure could accurately evaluate known or suspected intramural lesions of the gut,<sup>16,17</sup> and it was rapidly expanded to include the esophagus; problems

of diagnosis and recurrence of neoplasia, especially in the pancreas; portal hypertension; the colon and rectum; and bile ducts.<sup>41</sup> In 1991, Wiersema et al<sup>42,43</sup> showed that EUS could be used to obtain fine-needle aspiration cytology of mediastinal nodes and of nodes and lesions of the upper and lower GI tract. The addition of Doppler technology has now made possible the study of the flow through various structures, including the thoracic duct and blood vessels. EUS is increasingly being used to provide therapy, leading to the development of "interventional EUS." EUS-guided interventions include celiac plexus block/neurolysis, placement of fiducial markers to facilitate radiotherapy, direct injection of alcohol or chemotherapeutic agents for the treatment of tumors or cystic lesions, drainage of the pancreatic or biliary ductal systems, and the creation of gastrojejunostomies using lumen-apposing metal stents. The techniques of using EUS instruments differ only slightly from using videoendoscopes, but dedicated training is necessary to interpret the sonographic images obtained accurately. EUS is not amenable to self-instruction. EUS training centers have been established in academic centers, but retraining of practicing physicians is challenging due to the duration of training necessary to achieve competence.<sup>44</sup>

### Capsule Endoscopy (Wireless Endoscopy)

In 2000, Iddan et al<sup>45</sup> reported the development of a capsule containing a tiny CMOS camera that could be swallowed, obtain images (at 2 frames per second), and transmit the images over 7 hours to a receiving digital storage unit worn by the patient as he or she goes about his or her normal activities. These frames are downloaded to a computer from which they are projected onto a monitor at a rate that can be controlled by the observer. Pictures can be printed of areas of interest. Gastroenterologists in Israel conducted randomized trials comparing the efficacy of the wireless capsule with push enteroscopy and obtained superior results with the capsule.<sup>46–48</sup>

Wireless capsule endoscopy caught the imagination of gastroenterologists over the world, and capsule endoscopy has been adopted as a part of standard practice for small bowel imaging. The findings are virtually unanimous in demonstrating better results in identifying lesions in the small bowel with capsule endoscopy when compared to push enteroscopy.<sup>49</sup> The capsule avoids the discomfort and need for sedation inherent with push enteroscopy. In addition to lack of biopsy capability, an additional disadvantage is the time needed to review the study, but this has been overcome by a variety of methods including software advancements, improved training techniques, and utilizing non-physician personnel to initially review the obtained images. The major use of the capsule to date has been in elucidating the cause of occult bleeding from small bowel sources, where it seems to be superior to other methods. Future applications, such as in the colon, are continuing to be investigated in large, multicenter comparative studies. The future of wireless capsule endoscopy is bright. It will be interesting to see how the principle of wireless endoscopy is incorporated into videoendoscopes, such as the potential for a wireless connection between the endoscope and the image processor.

### Enteroscopy

The small intestine has traditionally been regarded as the final frontier of GI endoscopy. Although capsule endoscopy provides remarkable images of the small bowel mucosa, tissue acquisition

and therapy with a capsule-based instrument is many years away. Surgically assisted small bowel enteroscopy may be performed via either the transoral or anal route or via a mid-small bowel enterotomy incision. The disadvantage of this technique is its invasive nature.<sup>50</sup> Endoscopic examination of the small intestine has remained technically difficult. The many loops of the small intestine prevent progression of the instrument tip by simple pushing. This problem was overcome initially with the use of the Sonde enteroscope,<sup>51</sup> which is a very fine, floppy instrument with a balloon at the tip. The Sonde enteroscope progressed through much of the small bowel under peristalsis, and then the proceduralist would slowly withdraw the instrument, assessing the mucosa while pulling back. This technique was thought to visualize 50% to 70% of the mucosal surface.<sup>52</sup> However, the procedure was uncomfortable, time-consuming, and did not permit therapeutics, all of which limited its use.

The concept of small bowel enteroscopy was revolutionized by Yamamoto with the introduction of the double-balloon enteroscope in 2001.<sup>53</sup> This technique uses traction between a balloon at the tip of the enteroscope and another balloon on a flexible overtube to fix the loops of small bowel and provide traction for forward movement. The procedure requires peroral and anal procedures to examine the entire small intestine, and even then only in a minority of Western patients is the whole small bowel visualized. Nonetheless, double-balloon-assisted enteroscopy permits endoscopic therapeutics to most of the small bowel without the need for surgical assistance. A single balloon version is also available.

### Natural Orifice Transluminal Endoscopic Surgery (NOTES) and Peroral Endoscopic Myotomy (POEM)

A new development in endoscopy is natural orifice transluminal endoscopic surgery (NOTES), in which the endoscope is inserted into the abdominal cavity via an incision in an accessible organ. The first report appeared in 2002. Incisions have been made in the stomach, vagina, and colon with successful tubal ligation, liver biopsies, biopsy of peritoneal metastases, oophorectomy, cholecystectomy, and nephrectomy procedures having been performed. Most published articles report experimental use in animals, but more recent reports have described the simultaneous use of NOTES with laparoscopic techniques. Comparative studies are ongoing. A difficulty with the technique has been overcoming the lack of instrument "triangulation"; that is, approaching a surgical site from two or more directions to create countertraction, tie sutures, and so forth. Although NOTES is an exciting development, its remarkable potential will have to await the development of new instruments and the acquisition of additional expertise. At a minimum, it appears the development of NOTES will result in marked improvements in mucosal and transmural closure devices. Recently, flexible endoscopes have also been used to tunnel into the submucosal space of the esophagus and perform a myotomy, resulting in a treatment for achalasia termed peroral endoscopy myotomy, or POEM. First performed by Inoue in 2008 and reported by Inoue in 2010, this procedure has gained widespread popularity worldwide and has been performed thousands of times to date with impressive short- and long-term results and an excellent safety profile.<sup>54,55</sup> Additional applications of "submucosal" endoscopy include performing a similar procedure in the antrum to treat gastroparesis (G-POEM) and to perform resection of intramural lesions of the GI tract.<sup>56,57</sup>

## SUMMARY

The development of endoscopy is a testimony to human ingenuity. Instruments have evolved from dangerous straight tubes illuminated by light reflected from candles, to more flexible and safer instruments with an image transmitted through a series of prism lenses and illumination by an electric light bulb, to images transmitted through fiberoptic bundles with illumination transmitted by fiber bundles from an external source, to our present remarkably safe electronic instruments with digital images transmitted to a video screen through wires and processed by computers. Most recently, we can visualize the lumen of the gut without touching the patient. Now we can not only visualize, biopsy tissue, and perform surgical procedures within the hidden cavities of the body, but also directly and indirectly see beneath the mucosa and into immediately adjacent organs. The evolution of gastrointestinal endoscopy is a truly remarkable story, and advances in the diagnostic and therapeutic capabilities of these instruments continue to be made at a rapid pace. To know and understand what has occurred previously lends strength to efforts toward achieving what is to come.

## INTRODUCTION

The safe and efficient performance of gastrointestinal (GI) endoscopy has the following requirements:

- A properly trained endoscopist<sup>1</sup> with appropriate privileges to perform specific GI endoscopic procedures<sup>2,3</sup>
- Properly trained nursing and ancillary personnel
- Operational, well-maintained equipment
- Adequately designed and equipped space for patient preparation, performance of procedures, and patient recovery
- Cleaning areas for reprocessing endoscopes and accessories
- Trained personnel and appropriate equipment to perform cardiopulmonary resuscitation
- A robust quality assurance/improvement program<sup>4,5</sup>

Many of the previously listed requirements for safe and efficient GI endoscopy depend on the careful planning and design of the endoscopy facility. This chapter describes that process, beginning with laying the groundwork, including the development of a business plan and review of regulatory issues; site selection; facility planning and design (including patient flow and space needs); equipment requirements; staffing needs; and scheduling considerations. Some additional issues, such as endoscope cleaning and storage, tissue specimen processing and handling, record keeping and documentation, and quality assurance and improvement, are discussed briefly but are covered in more detail in subsequent chapters of this book (see Chapters 4, 5, and 10).

## EXPLORING POSSIBILITIES

### Type of Facility

There are different types of endoscopy facilities, including hospital endoscopy units, single-specialty or multispecialty ambulatory

surgery centers (ASCs), and office endoscopy suites. Each model has a unique set of advantages, disadvantages, and regulatory issues. The hospital and ASC environments are highly regulated by state and federal agencies and by third-party accreditation bodies. In the United States, these include The Joint Commission (JC), the Accreditation Association for Ambulatory Healthcare (AAAHC), and the American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF). Commercial payers sometimes impose their own specific requirements. Office endoscopy suites, previously less regulated, have been subjected to more controls by state and federal agencies in recent years.

The decision regarding which type of facility to establish is affected by the practice environment (solo practitioner, small or large group, single-specialty or multispecialty group, independent or hospital-based) and local economics and politics. Regardless of the service location, high-quality care must be maintained. The American Society for Gastrointestinal Endoscopy (ASGE) has stated that the "standards for out-of-hospital endoscopic practice should be identical to those recognized guidelines followed in the hospital."<sup>6</sup> The hospital-based unit poses the fewest financial risks and demands for the endoscopist during the early phases of operation, and its use avoids alienating hospital administration by preserving hospital case volume. This environment, however, affords the endoscopist little control over operations, and offers him or her the lowest financial return. Office endoscopy offers control and convenience with better financial return for the physician, but it poses some safety and liability concerns.<sup>7,8</sup> A single-specialty endoscopic ambulatory surgery center (EASC) provides the best of control, efficiency, convenience, and reimbursement for the physician owners and is extremely popular with patients, referring physicians, and payers.<sup>9,10</sup> A major ASC payment reform implemented by the

### Abstract

Since its introduction into clinical use in the early 1960s, GI endoscopy has transformed the discipline of gastroenterology and has become a crucial tool in cancer prevention and the management of GI disorders. The growing use of increasingly complex endoscopic procedures and the evolution of endoscopy in the outpatient setting have fostered the careful development of endoscopy facilities that enable the delivery of endoscopic services in a safe, efficient manner that is reassuring to the patient and produces good outcomes.

The process of setting up an endoscopy facility begins with exploring the types of facilities, developing a business plan, and researching relevant regulatory and certification issues. With those objectives accomplished, attention turns to planning the facility, including site selection, choosing equipment, and planning the physical environment and flow of patients and staff. Finally, the general plans for the facility are turned into specific architectural designs which form the basis for construction of a pleasant, efficient facility. Once the facility is constructed, careful attention to appropriate staffing, scheduling, documentation, and quality improvement activities promotes efficient and effective care as well as optimal patient outcomes.

quality

Centers for Medicare and Medicaid Services (CMS) in 2008 resulted in drastic cuts of facility payments for endoscopic services.<sup>11</sup> Subsequently, the passage of the Affordable Care Act in 2010 led to massive hospital consolidation, which, in turn, resulted in significant increases in the prices hospitals demand for endoscopic services provided in hospital-based facilities.<sup>12-14</sup> How all of these changes will affect both the efforts and the ability to provide beneficial GI services to patients at a reasonable cost remains to be seen. More information about recent and ongoing health care reform efforts is available elsewhere.<sup>15</sup> Regardless of the type of facility being developed, formulating a business plan and understanding various regulatory issues are usually the first steps in the process.

### Business Plan

The decision to set up an endoscopy facility should be made only after detailed data gathering and the formulation of a business plan (e.g., market analysis, financial pro forma, implementation time line).<sup>16-18</sup> For a hospital-based unit or academic medical center, facility planners and accountants often perform these functions. For an office-based suite or an EASC, the tasks fall to the physician owners, aided by numerous consultants, contractors, or corporate partners. Even with skilled help, however, development of an accurate and reliable business plan and pro forma are highly dependent on physician estimates, insights, and work habits. Physician input into the business plan makes the difference between a perfunctory exercise and an accurate predictor of future performance. Endoscopy facilities represent significant investments requiring substantial financial resources and staff. Procedure volume must be sufficient to produce adequate revenue to cover the costs of building and running the facility and to generate a profit on investment.

Many factors influence the financial performance of an endoscopy facility, including the size of the initial investment, expected volumes of service, revenue per unit of service, fixed operating costs, and variable costs per unit of service. The initial investment includes the cost of construction, equipment, and working capital for the first few months of operation. Strategic planning is important to anticipate group growth and demand for services in the next 5 to 10 years.<sup>16,18</sup> The impact on the GI practice of local competition and consolidation of health systems or major health plans must also be anticipated. In addition, population changes, demographics, and the possibility of new disruptive technologies might affect case volume for the practice and the endoscopy facility.

A pro forma is a calculation examining the financial feasibility of a project based on anticipated investment and operating costs and revenues. The purpose of the pro forma is to reliably predict cash flows and profitability for the project. Initial investment costs have been defined previously. Estimated total costs per case based on estimated fixed and variable costs and expected case volume are also incorporated in the pro forma. Fixed costs are costs that remain constant regardless of the number of procedures performed and include rent, interest, depreciation, taxes, insurance, amortization, and management fees. Staffing costs (salaries and benefits) are also largely fixed as most facilities operate with full-time staff for quality and efficiency reasons. Variable costs, including medical supplies, medications, equipment maintenance and repair, administrative supplies, etc., typically make up approximately 20% (i.e., a relatively minor portion) of the overall costs. Stated differently, doing one additional procedure adds a relatively small incremental cost for a significant financial benefit.

This is why optimizing efficiency as well as minimizing "no-shows" and empty slots on the schedule are critically important to the economics of an endoscopy unit.

Break-even volumes can be determined by subtracting the variable expense per procedure from the average payment per procedure to indicate the contribution available to be used for overhead and profit. Dividing fixed costs by the contribution margin per procedure indicates the number of procedures needed to pay the fixed costs, also known as the break-even point. Additional service units above that level constitute profit. Vicari and Garry<sup>16</sup> provided a simple example of a pro forma. The business plan and pro forma are mandatory in assessing the financial feasibility of the proposed endoscopy unit before construction. They further aid discussions in obtaining financing and help the architect design the unit for anticipated volumes.

### Regulatory and Certification Issues

Before planning and designing the facility, one must understand the relevant regulatory and certification issues. As with the business plan, units developed in a hospital or academic medical center usually benefit from administrators and planners familiar with these complex issues. Physician owners of an office endoscopy suite or EASC must gain their own understanding. Various agencies provide myriad rules and regulations concerning endoscopy facilities.<sup>19-23</sup> Legislation can come from federal, state, or local authorities. Regulations may come from federal agencies, state departments of health, third-party accreditation organizations, and private payers. Although these rules and regulations can seem excessive and needlessly costly, their intent is to ensure safe and successful outcomes for patients. Regulations and certification issues for endoscopy facilities can be divided into six main categories, as follows:

- General federal regulatory laws and rules
- Facility state licensure
- Medicare certification
- Third-party accreditation
- Physician credentialing
- Private payer requirements

### General Federal Health-Related Laws

Federal regulatory laws and rules include fraud and abuse statutes (also known as antikickback laws), which are laws designed to prevent excessive or inappropriate payments. Endoscopy centers typically fall into a specific "safe harbor," a designation that protects EASC investors or shareholders from allegations of fraud or abuse. The safe harbor applies if the physician participants are surgeons or specialists engaged in the same surgical or medical practice specialty, including gastroenterology. These physicians can refer patients directly to their center and perform procedures on them as both an extension of and significant part of their practices.

Additional requirements of the safe harbor apply. Ownership of the facility, or remuneration from it, cannot be related to volume of referrals, services furnished, or the amount of business otherwise generated from that physician to the EASC. The amount of payment to physician owners from facility revenues must be directly proportional to the amount of each owner's capital investment. There must be no requirement that a passive investor make referrals to the EASC, and the EASC or any investor cannot make loans or guarantee a loan for a physician if these funds are used to purchase ownership in the EASC. Each physician must agree to treat Medicare and Medicaid patients. Finally, the

physician owner must derive at least one-third of his or her medical practice income from the performance of procedures that require an EASC or hospital endoscopy unit setting.

Other general federal health-related laws and rules relevant to endoscopy facilities include the False Claims Act, copayment waivers, Stark provisions, Health Insurance Portability and Accountability Act (HIPAA) provisions, and labor and employment issues. The False Claims Act was designed to prevent false billings, claims that are medically unnecessary, and billings for inappropriately high payment. Copayment or deductible waivers may also be illegal if the government suspects such waivers are likely to induce referrals. Stark provisions stem from the Ethics in Patients Referrals Act. They are closely related to fraud and abuse statutes, but are civil rather than criminal laws. The regulatory body overseeing Medicare has ruled that a physician does not make an illegal referral for a procedure when he or she either personally performs the service or refers a patient to a partner to perform the service. HIPAA provisions are rules and regulations covering patient health information disclosed by any covered health care entity, provider, or facility. Regarding labor and employment issues, numerous rules and regulations cover discrimination, harassment, protection of the disabled, and workplace safety. The Occupational Health and Safety Act (OSHA) of 1970 seeks to protect employees from recognized work hazards that might cause death or serious harm. For endoscopy centers, OSHA requirements of major importance cover cleaning of endoscopic equipment, disinfection, and appropriate ventilation.

### State Licensure

The state department of health licensing authority is interested in several features of a potential endoscopy facility. First, before any design and construction is undertaken, a careful review of the state's certificate of need (CON) requirements is needed. Some states do not allow construction of new facilities unless need is demonstrated. This process can be difficult and prospective physician owners of endoscopy facilities may encounter opposition from hospitals fearing competition and seeking to maximize use of their own facilities. Regarding specific construction guidelines, state regulators are most often interested in patient safety, the flow of the facility, cleanliness, and control of infection within the procedure areas. Many states follow guidelines from the Facility Guidelines Institute (FGI), but individual states recognize different versions of these FGI guidelines. Many states will also have their own set of regulations that must be followed and may relate to specific room sizes, acoustic regulations, door and hall size requirements, handicapped access provisions, requirements for exhaust systems, and specific fire codes.

### Medicare Certification

Medicare certification is usually sought after obtaining state licensure and is required for any facility seeking reimbursement for Medicare and Medicaid work. Medicare regulations and requirements are usually more extensive than regulations of the state and address governance of the facility, transfer agreements with a nearby hospital, continuous quality improvement activities, Medicare architectural requirements, and medical records. Additional standards concern organization and staffing, administration of drugs, and procurement of laboratory and radiology services. Two other requirements warrant special attention as they relate to EASCs. First, the facility must be used exclusively for providing "surgical" services, a definition that includes GI endoscopies but not services like manometry. This requirement

also mandates a separation from other health care activities, separate staffing, and maintenance of special medical and financial records. Finally, the facility must comply with state licensure laws, which is potentially difficult in some states because of restrictive CON requirements. Medicare will survey under the ASC regulations for compliance<sup>24</sup> and the Medicare-adopted code set of the National Fire Protection Association (NFPA).<sup>25</sup>

### Third-Party Accreditation

After state licensure and Medicare certification have been obtained, some states or specific payers may require a third-party accreditation before authorizing payments to an endoscopy facility. This accreditation can be provided by inspection from JC, AAAHC, or AAAASF. Although these accreditations are typically achieved after state licensure, they can sometimes be pursued simultaneously with Medicare inspection. Under certain circumstances, Medicare accepts accreditation from one of the third-party accreditation authorities in lieu of its own survey; this is known as attaining "deemed status." In a deemed-status survey, the surveyors will survey for both state regulatory compliance as well as Medicare regulatory compliance. Third-party accreditations focus on patient-related and organizational functions and, in the case of an EASC, concentrate on the "environment of care" or "facilities and environment."

Third-party inspection of a facility can be challenging and demands that the owners and operators fully understand the standards of each specific accrediting organization. A JC survey scrutinizes a variety of domains including Environment of Care, Emergency Management, Human Resources, Infection Prevention and Control, Information Management, Leadership, Life Safety, Medication Management, National Patient Safety Goals, Provision of Care, Record of Care, Rights and Responsibilities, and Waived Testing and Performance Improvement. AAAHC and AAAASF inspections assess similar functions, although these may be grouped under different organizational headings.

### Physician Credentialing

Credentialing and privileging of physicians using an EASC may be mandated by federal, state, local, or third-party organizations and include a formal application process, verification of licensure and drug enforcement administration status, malpractice history, admitting privileges, advanced cardiac life support status, and documentation of training. Additional requirements may be outlined in the center's medical staff bylaws (for example, board certification of providers).

### Payer Requirements

Individual health plans or insurers may have their own requirements, and these may vary significantly from payer to payer. Careful attention to local payer mix and any special requirements is necessary before designing and building an endoscopy facility to ensure qualification for payment. As outlined previously, the regulatory and certification issues for endoscopy facilities are "complex, detailed, and broad."<sup>26</sup> Any physician wishing to develop an endoscopy facility must understand these rules of regulation and certification. Appropriate legal counsel should be considered essential.

### Choosing a Site

For hospital-based endoscopy facilities, the location of the facility is usually determined by the hospital's own planners. Although some hospitals have developed separate units for outpatient and

inpatient endoscopies, most hospitals operate a single endoscopy unit. Choosing its location requires careful consideration of patient transport issues; the flow of inpatients and outpatients in and out of the unit; and the proximity to radiology, the emergency department, intensive care units, and inpatient wards. With office-based endoscopy or EASCs, physician owners choose the site. The site size and location require careful consideration because most office-based facilities or EASCs later expand to accommodate more physicians and patients. Preliminary land requirements are determined from space estimates (discussed later), parking requirements, appropriate landscaping or "green areas," and anticipated expansion. For an office endoscopy suite or EASC, proximity to a hospital is desirable to minimize travel for patients requiring hospital transfer and for physician convenience. The site should be near but perhaps not on a major street to ease patient parking. Many patients coming to an EASC or office-based facility are elderly or may be anxious about their upcoming procedures. Access should be easy. Locating the physician offices adjacent to the EASC should be strongly considered because it may be very efficient for staff and patients.

### Facility Planning and Design

After forming a realistic business plan and acquiring an understanding of relevant regulatory and certification issues, attention turns to the planning and design of the facility. Although the remainder of this chapter includes some remarks about issues specifically related to hospital units, the main focus of the discussion is on the development of an outpatient endoscopy facility, details of which are equally applicable to hospital units. Objectives must be articulated to the design professionals to ensure that the facility meets the needs of patients, endoscopists, and staff. Some points to keep in mind are the following:

- Allow adequate time for planning.
- Set aside a regular block of time for discussion, review, and program development.
- Choose experienced design professionals with health care experience and knowledge of state and local health care building regulations.
- Involve staff to ensure attention to their needs and wishes.
- Prepare a statement of needs and goals to aid the architect in preparing a detailed program.
- Prepare an inventory of equipment needed and its location for the architect to be able to install the proper electrical system and plumbing.
- Visit other facilities to gather ideas worth incorporating.
- Use flow studies to evaluate placement of functional elements.
- Review preliminary drawings carefully.
- If questions arise about the size or shape of a space, lay it out with tape on the floor and simulate work practices.

Planning and design of the facility is a team project. The team mainly involves a physician representing the endoscopists who will use the facility; two staff people, including the nurse responsible for patient care activities within the unit and the appropriate administrator; the architect; engineers; and the builder. The responsible physician must be given adequate time away from clinical duties to devote to planning, design, and oversight of the construction of the facility. Designated time must be set aside because the process is ongoing and cannot be relegated to lunch hours and brief sessions whenever time can be stolen from clinical activities. The architect is the primary professional involved in overseeing the entire project. It is wise to select an architect

who specializes in medical buildings, particularly one who has experience in designing endoscopy facilities. Similarly, selection of a contractor who has experience in medical construction, particularly construction of endoscopy facilities, is important. Both the architect and the contractor must thoroughly understand the requirements of regulatory and certifying bodies and local and state building codes. Sometimes the design and contracting can be provided by one company with both design and building capabilities.

Although the physician representative, designated staff persons, architect, and contractor compose the major elements of the planning and design team, additional input may be needed from engineers (mechanical, electrical, plumbing), telephone contractors, information technology experts, and attorneys. Consideration might also be given to involving a layperson or "patient" to ensure sufficient attention to issues of patient comfort, dignity, and privacy.

### PLANNING

The planning stage is concerned with deciding what activities will be conducted in the facility, what equipment will be needed, and how space will be allocated.

### Scope of Activities

The first consideration is which endoscopic procedures and other services will be performed in the facility. The type of facility will, to a great extent, answer this question. For a hospital unit that must provide a wide range of endoscopic services, one or more rooms must be large enough and appropriately equipped to accommodate the special equipment required for complex procedures (e.g., endoscopic retrograde cholangiopancreatography [ERCP], endoscopic ultrasound [EUS], balloon enteroscopy, laparoscopy, anesthesia cart). In some community hospitals, endoscopy units are shared with other specialties, such as cardiology or pulmonology, and have to accommodate procedures such as transesophageal echocardiography or bronchoscopy. If the hospital is part of an academic medical center, the unit may serve additional purposes, including teaching and research, requiring further modifications in space, equipment, and staffing.

For an office suite and EASC, services offered will be based on clinical considerations, safety, and logistics. In these out-of-hospital facilities, procedures are usually limited to individuals and stable patients undergoing "routine" high-volume procedures with predictable turnaround and recovery times, utilizing standard equipment and accessories. In an EASC, it is crucial that all procedures done be on the Medicare approved list to qualify for facility reimbursement. For both the office suite and the EASC, procedures are often limited to upper GI endoscopy, esophageal dilation, and colonoscopy, including polypectomy. Predictably, rapid turnaround time is crucial for an efficiently functioning EASC or office facility. Whereas EUS, ERCP, and other complex endoscopic examinations are also done in some EASCs, it is generally advisable to perform long procedures or procedures that are unpredictable in duration or clinical outcomes in the hospital. Procedures requiring prolonged recovery times, such as liver biopsy, are also best done in a hospital environment.

The question sometimes arises whether it is better to have a multispecialty or single-specialty ASC. From the standpoint of services offered and equipment, a single-specialty EASC has the advantage of being the "focus factory." In this environment,

endoscopists, skilled GI nurses, technicians, and administrative staff maximally use standardized equipment, performing predictably timed procedures with a rapid turnaround. A single-specialty EASC avoids the problem of a multispecialty facility in which highly specialized equipment lies idle much of the time while physicians from differing specialties are performing their individual procedures.

### Equipment

The greatest capital expense after the basic construction is equipment. Some tabulation of the equipment needed is necessary in the early planning stages and facility design. The basic equipment needed for an endoscopy unit is listed in Box 2.1. A detailed discussion of individual items is not presented here, but a few points are useful in integrating the equipment needs into planning and design. Generally, examining or procedure tables have been replaced by height-adjustable, rolling procedural stretcher carts that allow patients, once properly gowned for endoscopy, to mount the movable cart and not leave it until ready to leave the facility. These carts allow patients to be shuttled from preparation

areas to procedure rooms and back to recovery areas, and also serve as procedure tables. This capability is very important to overall system efficiency and adds to patient safety by avoiding transfer to and from a procedure table.

Another major determinant of overall system speed and efficiency is the availability of endoscopes. Adequate numbers of endoscopes, high-level disinfection systems (automatic endoscope reprocessors [AERs]), and adequate storage for extra endoscopes are required. Adequate numbers of endoscopes must be available to prevent inefficient downtime in the unit. Staff salaries, wages, and benefits make up a significant percentage of total costs of providing endoscopic services, and it is inefficient and fiscally unwise to have highly paid physicians and staff waiting for endoscopes. Regarding dilating devices and other accessories, decisions (e.g., whether to use a Savary dilator system versus dilating balloons) should first and foremost be made on clinical grounds. This decision will, however, also have economic consequences as the cost of accessory devices is bundled into the facility payment and the endoscopy center will not be able to procure additional reimbursement for higher-cost devices. Finally, with the growing use of propofol and anesthesia services for endoscopic procedures, additional medications and equipment are often required for this service.<sup>28,29</sup>

### Physical Environment

Before beginning specific planning and design, some issues affecting space efficiency should be considered. It is the goal for physicians and staff to work as quickly and efficiently as possible while giving patients the assurance that they are receiving appropriate and safe care. System speed in the endoscopy facility usually comes from the following three delivery components:

1. Preparation and recovery of the patient.
2. Reprocessing and return of endoscopes to the procedure room.
3. Physician work habits.

If the first two components operate properly, the number of procedure rooms available is not as important as the practice habits of the physician in starting their schedule on time, performing procedures in an efficient manner, talking to patients and their families, completing medical records, and returning to the procedure room.<sup>30</sup> In an efficient facility, physician discipline is needed because room turnover and equipment reprocessing time can be rapid.

### Flow

Architects use flow diagrams to plan movement patterns in arranging space before actual design plans. Physician and nurse input is crucial in arranging the flow relationships within the endoscopy facility to maximize efficiency, minimize travel distance, and achieve economy of movement. A basic flow diagram showing patient flow through a simple endoscopy unit is shown in Fig. 2.1. The patterns of movement may be more complicated in a hospital department. Simple flow diagrams such as these can be elaborated into a functional schematic drawing diagram as shown in Fig. 2.2. This type of functional schematic diagram shows the way that patients, staff, physicians, and equipment can move through the facility. A functional schematic diagram can be turned into a floor plan by assigning actual space requirements to the rooms that are represented. A 40% circulation allowance must be added at the end of the tabulation to account for wall thicknesses, corridors, and so forth.<sup>30</sup>

For hospital-based units, specific patient flow issues must be considered. Separate entrances for sick, bedridden patients and

### BOX 2.1 Endoscopy Facility Basic Equipment List

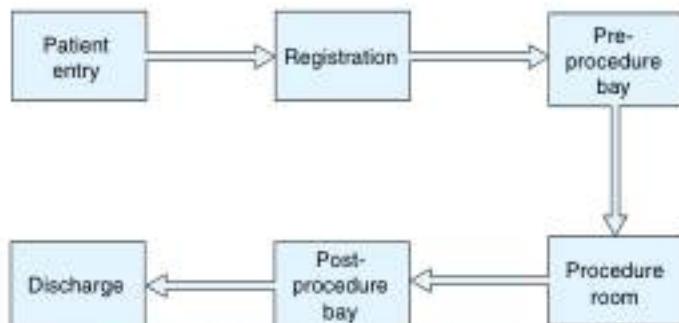

- I. Major endoscopic and electrosurgical equipment
  - A. Endoscopes, light sources, video processors, and monitors
  - B. Electrocautery units and accessories
  - C. Hemostasis unit (e.g., heater probe, gold probe, argon plasma coagulator)
  - D. Physiologic monitoring devices including pulse oximetry, blood pressure, and cardiac monitoring
- II. Catheters, snares, forceps, and brushes
  - A. Polypectomy snares
  - B. Biopsy forceps
  - C. Brushes
    - 1. Cleaning
    - 2. Cytology
  - D. Graspers
  - E. Retrieval baskets
- III. Endoscopic report writer with photo generator and image manager
- IV. Esophageal dilators
  - A. Wire-guided (e.g., Savary)
  - B. Balloon
- V. Rolling procedural stretcher carts with adjustable heights
- VI. Suction equipment
- VII. Pharmaceuticals
  - A. Sedation and analgesia agents
    - 1. Benzodiazepines
    - 2. Narcotic analgesics
    - 3. Miscellaneous preference
  - B. Benzodiazepine antagonists
  - C. Narcotic antagonists
  - D. Glucagon
  - E. Atropine
  - F. Topicals
- VIII. Intravenous equipment, solutions, needles, and syringes
- IX. Chemicals
  - A. Formalin
  - B. Disinfection solutions
- X. Emergency cart, resuscitation equipment, supplies, and medications
- XI. High-level disinfection equipment (cleaning trays, sinks, automatic endoscope washers, and autoclave)
- XII. Instrument storage cabinets
- XIII. Blanket warmer
- XIV. Audio/music system
- XV. Eyewash station

ambulatory individuals should be considered. The monitoring and treatment requirements for sick inpatients must be taken into consideration. Separation of inpatients and outpatients in waiting or holding areas, preparation areas, and recovery areas may also be helpful. If an endoscopy facility is constructed adjacent to a clinic facility, the regulations require a firewall separation between the EASC and the clinic. Shared waiting rooms are no

longer permitted. This separation may require a 1- or 2-hour fire rated wall-door construction system depending on the state and/or the building in which the facility is located. When fire-rated walls are required, it is important that the proper rating of the wall is considered, making sure the fire-rated gypsum board on either side of the structural wall extends through the ceiling to the roof of the structure above and all penetrations through the wall are properly sealed.

### Designing the Endoscopy Facility

The *Guidelines for Design and Construction of Health Care Facilities (FGI Guidelines)*, published by the American Society for Healthcare Engineering, include a section on the design and construction of GI endoscopy facilities.<sup>31</sup> The document is updated on a 4- to 5-year revision cycle with the latest edition published in 2014. Many states have not yet adopted this newest version and some have not officially adopted any version. A state map outlining FGI adoption is also available.<sup>32</sup> The *FGI Guidelines*, which are referenced by many federal and state jurisdictions, were originally conceived as minimum construction requirements for hospitals. Over time, the document has evolved to include engineering systems, infection control, and safety and architectural guidelines

**FIG 2.1** Basic endoscopy unit flow diagram.

**FIG 2.2** Functional relationship diagram for an ambulatory endoscopy center.

**TABLE 2.1 Space Considerations**

Room	Components	Considerations
Waiting	Seating Beverage counter Public restroom	Calculate the amount of seating in the waiting room based on the number of procedure rooms being constructed. Typically, 3 chairs per procedure room are needed.
Reception/business area	Registration bays needed Billing area Medical record storage	The number of registration bays may vary depending on the number of procedure rooms. If billing functions are outsourced, less space is needed for this function. If the facility is using an EMR, medical record storage can be reduced to locking millwork.
Pre/post procedure area	Pre/post procedure bays Nurse station Nutrition area Medication area Patient belongings Handwashing sinks Restrooms/patient changing Exam/consult room	Number of procedure bays will vary with State regulations. Typically, 2–3 bays are required per procedure room. Pre- and post-op bays can be used interchangeably, provided the minimum monitoring, electrical and medical gas components are included. Nurse station must have visualization of all bays. One nurse station for all bays provides a more efficient staffing model. Medication area may be provided behind nursing station in locking millwork if State allows. Small purse lockers can be provided to secure patient belongings. Handwashing sinks typically required = 1 sink per every 4 bays.
Procedure area	Corridor Procedure rooms	The number of procedure rooms will drive the project. This calculation will be based on number of physicians and physician volume. Minimum size requirements for these rooms will vary by State. A corridor separating the pre/post area from the procedural area may be required by State. Scrub sinks – may be required in some States.
Reprocessing area	Soiled scope Reprocessing area	Separation of the soiled scope area and reprocessing area are essential. A pass-through window will allow these rooms to have two separate and distinct functions. Eyewash should be provided in the reprocessing area due to the chemicals used for reprocessing.
Staff area	Locker room(s) Shower Staff restrooms	Number and size of locker rooms will vary depending on the number of procedure rooms/staffing. Staff shower is required in some States.
Supporting functions	Storage Environmental functions Utility rooms IT room Biohazard/soiled linen/trash room	Minimum storage requirements must meet State requirements. Two environmental closets are typically required.
Mechanical	Medical gases Water heater/boiler UPS/generator Electrical room Vacuum pump room HVAC	Medical gas room is required to be rated. Depending on the number of gases, storage in this room may be required to meet certain ventilation requirements. Consider adding CO <sub>2</sub> to the manifold to allow for CO <sub>2</sub> insufflation in the procedure room. Work closely with the engineers to determine mechanical requirements.
Exterior	Parking Canopy	Adequate parking spaces must be provided. Number of spaces required will depend on local jurisdiction. Handicap spaces must be provided. Canopy extending to the curb may be required by some States.

EMR, electronic medical record; UPS, uninterruptible power supply.

for design and construction of hospitals and other types of health care facilities. It provides an invaluable resource for the construction of a new EASC, the construction of a hospital-based endoscopy unit, or the renovation of existing units. The *FGI Guidelines* can be purchased through the American Hospital Association.<sup>11</sup>

Table 2.1 provides a list of areas and components of a typical endoscopy unit as well as some key considerations for each area. The following sections highlight some of these considerations.

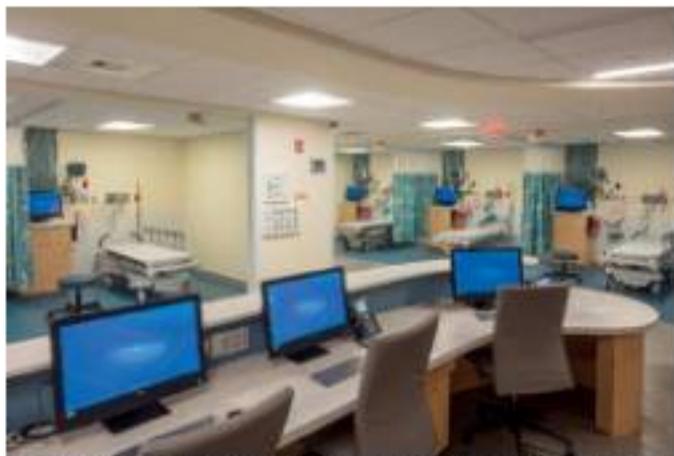

#### Arrival and Waiting Areas

The patient's experience of the endoscopy facility often begins outside the building in the parking lot. Patients arriving for endoscopy are often anxious and sometimes frightened. Maps with careful driving instructions and signs posted in the vicinity of the endoscopy facility can minimize confusion and offer reassurance. An all-weather canopy and automatic opening doors are helpful to elderly, ill, or disabled patients. The reception and

waiting room area provides an early impression of the endoscopy facility and should project friendliness and efficiency. Wheelchair storage should be available in this area, with wheelchairs stored out of sight. There must be adequate room for patients' escorts because one or two people usually accompany each patient scheduled for endoscopy. If the clinic area is adjacent to the endoscopy center, there are very specific mandates in regard to separate and distinct waiting rooms. As an example, per CMS manual, the endoscopy center "must provide a waiting area for its patients within the perimeter of its 1-hour fire-rated barrier and ensure said barrier is free of penetrations."<sup>14</sup> Waiting areas should be well appointed and equipped with a television set and reading material. A toilet should be available near, but not directly off, the waiting room. Drinking water should be provided, either via a drinking fountain (required in some states) or bottled water (allowed in some states). The general waiting area for Northern New Jersey Endoscopy Center, Englewood Cliffs, NJ is shown in Fig. 2.3.

**FIG 2.3** General waiting area for Northern New Jersey Endoscopy Center, Englewood Cliffs, NJ. (Photograph by Andrea Brizzi; facility designed by RSC Architects, Hackensack, NJ, <http://www.rscarchitects.com>.)

**FIG 2.4** Nursing control station for preparation-recovery area, Northern New Jersey Endoscopy Center, Englewood Cliffs, NJ. (Photograph by Andrea Brizzi; facility designed by RSC Architects, Hackensack, NJ; <http://www.rscarchitects.com>.)

### Business-Reception Area

The business-reception area includes the reception desk, registration bays, billing stations, and medical records storage. If billing functions are outsourced, square footage can be eliminated for this function. With the adoption of electronic medical records, the space needed to store paper copies of medical records can be kept at a minimum. Often this space is limited to locking cabinets located in this area.

### Pre/Postprocedure Area

The preparation-recovery area of the endoscopy facility requires constant patient surveillance from the nursing staff. This area usually contains a nursing control station (Fig. 2.4), which allows unobstructed viewing of patients during the preparation and recovery stages of their visit. The most efficient arrangement for preparation and recovery is to have them occur in the same place and to set up the patient bays so they can be used interchangeably. Patient clothing can be stored in a locked cabinet

in the preparation-recovery area or can accompany the patient during transport to the procedure room and back, stored in a belonging bag underneath the rolling procedural stretcher cart. Patient valuables should be left with the patient escort or secured in a locker during the procedure. Patients can be rolled into procedure rooms on properly designed stretchers that are also used as procedure tables. In this way, patients can move from preparation to procedure and back to recovery requiring no mounting or dismounting from wheelchairs or carts. This is not only more efficient but also safer for the patient.

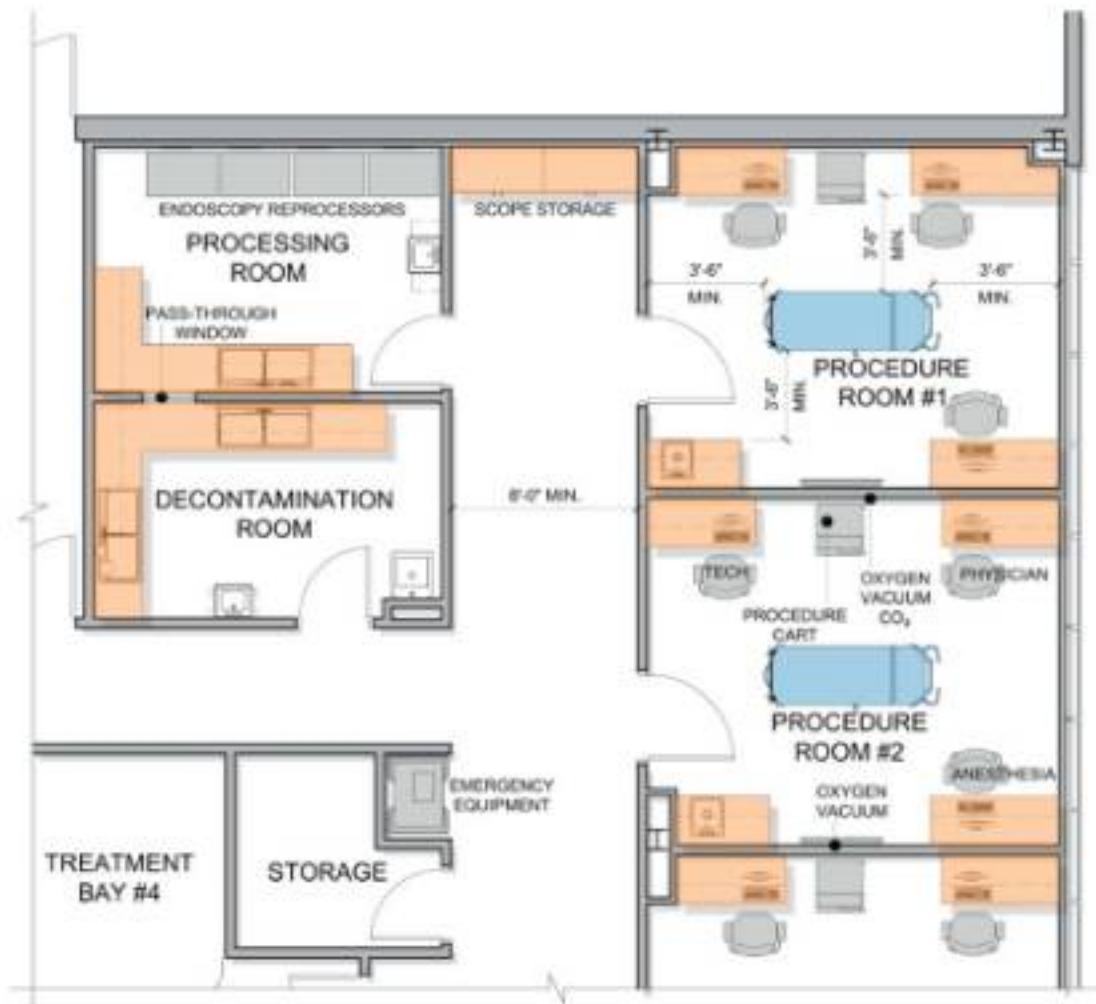

Per the FGI 2010 guideline, one preparation and two recovery rooms or curtained bays are required per procedure room, but state requirements may vary and need to be checked. Some patients who need additional recovery time after they are able to dismount the procedure cart can recover in recliner chairs. A few curtained recliner chair areas can provide this extra recovery space. The number and type of required recovery bays may also vary depending on the type of sedation used. Corridors between procedure areas and preparation-recovery spaces should be wide enough to provide easy patient cart movement. Toilets should be close to both preparation-recovery and procedure areas.

### Procedure Room Area

The number of procedure rooms is determined by the caseload of the endoscopy facility. This number is often overestimated. More important than the number of procedure rooms is the amount of recovery space available. In an efficient facility where turnaround time is quick, the number of procedure rooms can be minimized. Turnaround between cases should be very rapid. Using procedure rooms for recovery compromises efficiency by tying up a specialized procedure room. To determine the required number of procedure rooms, consider the number of physicians and the anticipated procedural volume. An average efficient procedure room should be able to accommodate 16 to 20 endoscopy procedures per day, depending on the types of procedures being performed. Allowances should be made for anticipated growth in numbers of physicians and patients over the subsequent 5 years. By using the patient load anticipated 5 years hence, and dividing this load by the number of procedures per room per year, the number of required rooms can be calculated.

The minimum size for an endoscopy room is approximately 200 clear square feet according to the FGI Guidelines; however, this may vary according to state specific regulations. Clearances shall permit a minimum clearance of 3 feet 6 inches at each side, head, and foot of the stretcher/table. A hand-washing station shall be available to each procedure room. Approximately 300 square feet may be needed for higher complexity endoscopy procedures. Sometimes state licensing departments or Medicare mandates a minimum size for an "operating room" that is inappropriately large for an endoscopy room. In that instance, a variance can be requested, but it is not automatically granted.

In an endoscopy procedure room layout, placement of the light source, the video processor, video monitor(s), and electrocautery must be carefully considered. Many variations are possible to fit the preferences of the endoscopists and nursing staff. Rooms should be planned with equipment and supplies integrated into the layout and positioned strategically around the site of the patient on the procedural stretcher. An example of such a procedure room layout is provided in Fig. 2.5. The floor should be free of cables and wiring; these can be arranged along the perimeter of the room or preferably above ceiling, below the

**FIG 2.5** Example of procedure room and reprocessing room layout.

floor, or via conduits in the walls. This allows physicians, staff, and equipment to move unfettered by cords and cables, and it avoids damaging these sensitive components. Preplanning should include consideration of the type of endoscopes used, as this will affect the cabling needed. All endoscopic accessories, suction, oxygen, supplies, and all resuscitation equipment should be at hand. An emergency call button is required in each procedure room, and an emergency (crash) cart should be stored nearby. A typical endoscopy procedure room is shown in Fig. 2.6.

#### Reprocessing Areas

Efficient equipment turnover time can be achieved by having appropriate equipment for rapid cleaning and high-level disinfection. In this scenario, the speed of the endoscopy facility is determined by the efficiency of the physician between procedures rather than by the number of procedure rooms. Instrument cleaning and high-level disinfection can be accomplished by strategically placing the cleaning area between two procedure rooms or having an efficient large cleaning area within a short distance of several procedure rooms. Adequate numbers of endoscopes stored properly and reprocessed effectively and efficiently ensure that the most expensive cost elements of the endoscopy facility—the physicians and nursing staff—are not kept waiting for equipment.

**FIG 2.6** Typical endoscopy procedure room, Northern New Jersey Endoscopy Center, Englewood Cliffs, NJ. (Photograph by Andrea Brizzi; facility designed by RSC Architects, Hackensack, NJ; <http://www.rsearchitects.com/>.)

**FIG 2.7** High-level disinfection processing room for multiple endoscopes. Northern New Jersey Endoscopy Center, Englewood Cliffs, NJ. (Photograph by Andrea Brizzi; facility designed by RSC Architects, Hackensack, NJ; <http://www.rscarchitects.com>.)

**FIG 2.9** Endoscopy storage cabinet providing air circulation through endoscopy channels. Northern New Jersey Endoscopy Center, Englewood Cliffs, NJ. (Photograph by Andrea Brizzi; facility designed by RSC Architects, Hackensack, NJ; <http://www.rscarchitects.com>.)

**FIG 2.8** Pass-through window maintains separation of "clean" and "dirty" areas. Northern New Jersey Endoscopy Center, Englewood Cliffs, NJ. (Photograph by Andrea Brizzi; facility designed by RSC Architects, Hackensack, NJ; <http://www.rscarchitects.com>.)

The soiled scope cleaning room and the reprocessing room should be large and appropriately ventilated, with ample plumbing and power provisions for future changes. Oversized sinks are required, and there should be a place for soiled endoscopes to be placed while waiting to be cleaned. Automated endoscope-reprocessing machines with multiple endoscope compartments provide an efficient way of reprocessing endoscopes (Fig. 2.7). Different instrument-reprocessing units vary in the chemicals used and their cleaning time, which has an impact on the number of endoscopes required by a busy unit. A "pass-through" window from soiled to clean processing areas, as shown in Fig. 2.8, can help maintain separation of clean and dirty areas.

A closed cabinet with proper ventilation for the storage of the clean endoscopes is essential. Endoscope storage cabinets that circulate air through the endoscope channels provide added

protection against moisture and bacterial growth within channels. A storage unit with channel air circulation is shown in Fig. 2.9. It is essential that proper ventilation follow the standards to meet infection control and safety guidelines.

### Support Areas

General storage for supplies must meet all temperature/humidity guidelines and be readily accessible to the preparation-recovery areas and the procedure rooms. An adequately rated room should be provided for biohazardous waste. Space should also be allocated for soiled linen and regular trash. Environmental closets are also required for this space.

### Mechanical Areas

Mechanical rooms are needed to supply the medical gas manifold, vacuum pump, water heater, HVAC unit and other mechanical equipment. An alternative power source (Essential Electrical System), such as a battery backup system or generator, is necessary to ensure uninterrupted power. Providing the correct power source will be dependent on the type of anesthesia used, the type of facility, and Medicare and state regulations.

### Staff Area

Requirements for dressing room spaces are different in regulated and unregulated endoscopy facilities. Rules for the EASC or hospital may be quite different from the office. It is wise to know the regulations from the state department of health and from certification agencies. Male and female locker areas are generally required, but variances can be requested to eliminate the need for unnecessary shower facilities. Fig. 2.10 shows a convenient

**FIG 2.10** Staff changing room and lockers. Northern New Jersey Endoscopy Center, Englewood Cliffs, NJ. (Photograph by Andrea Brizzi; facility designed by RSC Architects, Hackensack, NJ; <http://www.rscarchitects.com>.)

locker/bench/shoe storage area in a staff locker room. An additional part of the staff area is the break room. Some state departments of health or certification bodies require a break room within the confines of the endoscopy facility. Careful attention to state and federal regulations is warranted to ensure that licensure and certification requirements are met.

### Summary of Planning and Design

The design of an efficient endoscopy facility is facilitated by a functional relationship diagram showing the flow of patients through the facility. An architectural space program is developed by tabulating the areas necessary and assigning space required. This architectural space program determines the size of the facility. A procedure room utilization calculation determines the number of procedure rooms and other areas necessary to handle the patient caseload, and provisions should be made for caseload growth. Careful attention to planning and design results in the construction of a pleasant, efficient endoscopy facility that meets the needs of patients, physicians, and staff.

### STAFFING AND SCHEDULING

Decisions regarding staffing and scheduling are critical to the safe and efficient operation of the endoscopy facility, have a major impact on patient outcomes, and affect the financial viability of the endoscopy unit.

#### Staffing

Decisions regarding staffing hinge on regulatory requirements, volumes of procedures, and case mix (disease acuity). Numerous federal and state regulations affect staffing decisions, and a

thorough knowledge of these requirements is necessary to ensure compliance with state licensing requirements, Medicare certification regulations, and third-party accreditation standards.<sup>34,35</sup>

Medicare guidelines stipulate that a registered nurse (RN) must be available on site during all hours of operation of a hospital or ASC endoscopy facility. The nurse practice act of each individual state also affects staffing decisions. A state nurse practice act defines the scope of practice for RNs, licensed practical nurses (LPNs), and other assistants or technicians. These nurse practice acts may limit who can start intravenous (IV) lines, administer IV medications, or provide other clinical services. To determine the number of full-time equivalents (FTEs) needed for staffing, one must quantify the time needed to care for a single patient, multiply this by the number of procedures scheduled daily, and divide by the work hours per day of a full-time employee. Some factors that influence the decision to use RNs versus LPNs versus technicians include scope-of-practice regulations, salary costs, and availability. Regardless of the mix, care should always be directly supervised by an on-site RN.<sup>36</sup>

#### Scheduling

Most facilities use block scheduling to maximize efficiency and convenience.<sup>34,35</sup> Block scheduling also allows for time allotments based on the performance characteristics of individual endoscopists. Examples of block scheduling and tools for use in block scheduling have been published by McMillin.<sup>31</sup>

Time allotments for procedures vary from facility to facility. Some facilities allow 45 minutes for colonoscopy and 30 minutes for upper GI endoscopy,<sup>31</sup> whereas others schedule more tightly, often using 30 minute slots for all upper and lower endoscopies (Digestive Health Specialists, Tacoma, WA, unpublished data). The tighter scheduling can be accommodated by efficient endoscopists, good staffing, adequate equipment, rapid turnaround time, and ample preparation-recovery space. Careful staffing and scheduling are imperative to ensure high quality care, good patient outcomes, and optimal fiscal performance of the endoscopy facility.

### DOCUMENTATION AND INFORMATION TECHNOLOGY

An accurate and complete medical record for each patient and a log of the unit's overall activities must be kept (see Chapter 10). The endoscopy report and nursing notes may include, but may not be limited to: date, patient identification data, endoscopist, specific instruments used, endoscopic procedure, indications, informed consent, extent of examination, duration of procedure, findings, notation of tissue sampling, therapeutic interventions, complications, limitations of the examination, conclusions, and recommendations. Photographs, electronic images, and biopsy reports should also be part of the record. Quality indicators and patient outcomes should be tabulated, and a method of regular peer review should be developed.<sup>37</sup> Information management in an endoscopy facility affects all aspects of the operation, including scheduling, billing and reimbursement, patient medical records, procedure reports, clinical laboratory and anatomic pathology reports, imaging, pharmacy, patient education, performance improvement data, financial management, materials management and inventory, budgeting and forecasting, payroll and personnel, and staffing and scheduling.<sup>37</sup> Modern information technology may allow more efficient and effective operations within the facility.

Information technology is changing medical practice at a rapid pace and may allow for more efficient and effective operations within the endoscopy facility.

To minimize repetitive data entry and difficulties with sharing and analyzing data across different systems, the modern endoscopy unit should plan ahead and install an information technology system that provides compatibility between the office electronic medical record (EMR), the endoscopic facility, the billing department, the endoscope manufacturer, the cardiac monitor manufacturer/model, and possibly the local hospital. The interface should allow prompt transfer of demographic data and pertinent components of the medical history and physical examination. Bidirectional transfer of information ensures that the procedure report and billing information are transmitted to the individuals who need access to it. Further increases in functionality can be envisioned. For example, the use of wireless networks and voice-recognition software for endowriters and EMRs are possible. Electronic systems can also be used to enhance service offerings to patients and families. The system can generate automatic reminder letters or offer educational material and resources for the patient and family if a new diagnosis has been made. The pathology request, endoscopy report, referral letter, discharge instructions, plans for follow-up, and billing information can be generated from the base examination and completed before the patient leaves the facility. Many of the documents can be sent electronically.

## QUALITY MEASUREMENT AND IMPROVEMENT

Increasing health care costs, constrained resources, and evidence of variations in the quality of care rendered have triggered a renewed emphasis on quality measurement and improvement. Two reports by the Institute of Medicine advocate widespread changes in health care, including paying for performance as a means of achieving the delivery of high quality care.<sup>38,39</sup> Medicare regulations and third-party accreditors require endoscopy facilities to engage in an ongoing comprehensive self-assessment of the quality of care provided. This process includes quality improvement efforts directed toward numerous facets of the operation of the facility. Reasons for quality improvement activities include ensuring that patients receive the highest quality of care possible; providing a competitive edge when seeking contracts; and addressing the recent emphasis of legislators and regulators on quality improvement activities as part of the licensure, certification, and accreditation process. Johanson<sup>40,41</sup> described continuous quality improvement in the EASC. The philosophies and tools presented in this article provide a framework for quality improvement activities in all endoscopic facilities. A 2015 publication by a joint task force from the ASGE and the American College of Gastroenterology provides an excellent resource with recommendations and ranking of quality indicators that can be used as a starting point in quality measurement and improvement efforts.<sup>3</sup>

## ACKNOWLEDGMENTS

The authors gratefully acknowledge the work of James T. Frakes, MD who authored and coauthored the previous versions of this chapter. The text of the current revision draws substantially from those previous versions. The authors are also very grateful to MaryAnn Gellenbeck for her suggestions and input related to the current revisions.

Endoscopes are flexible instruments combining fiber-optics (for illumination) and charge-coupled devices (for imaging) that are used in medicine to visualize the interior of otherwise inaccessible sites, such as the lumen of hollow organs. Endoscopes are used to examine the gastrointestinal (GI) tract, the bronchial system, the ureters and other body cavities. They have numerous uses in non-medical settings as well and are central to the modern management of many GI disorders.

## ENDOSCOPE DESIGN

The endoscope consists of three basic parts: the tip, the insertion tube and the control section (Fig. 3.1).

### The Control Section

The control section is the most versatile part of the endoscope. It is typically held in the left hand of the endoscopist and is used to maneuver the endoscope and introduce accessories. The tip can be maneuvered using the twin dials located on the control section. The larger dial deflects the tip up and down, whereas the smaller dial is responsible for lateral control (i.e., left or right) (Fig. 3.2). These dials can be locked into place to hold a particular position of the tip. Some ultra-thin specialized endoscopes may have only a single dial for up/down angulation and require application of torque for sideways maneuverability. Duodenoscopes used for endoscopic retrograde cholangiopancreatography (ERCP) and linear echoendoscopes have an additional dial for controlling the elevator.

There are two openings in the front of the control section that accommodate specially designed buttons. One button is used for applying suction at the tip of the endoscope. The second button has the dual functions of air insufflation and washing

the camera lens. There are separate buttons that can be used to freeze and record images, selectively change the wavelength of the light (see later section on **Image Processing**), and alter the focus of the camera. Some buttons are also programmable for specific functions.<sup>1</sup>

The control section is attached to the insertion tube. It also contains an entry port ("instrument channel") that allows passage of many different endoscopic accessories, such as biopsy forceps, electrocautery probes, and snares, through the length of the endoscope. Some colonoscopes incorporate a variable-stiffness function that is controlled by a rotatable dial at the level of the control head.

### Insertion Tube

The insertion tube is the part of the endoscope that enters the body. It contains a "working channel" of variable diameters, which permits passage of endoscopic accessories. It is also involved in the application of suction. Some endoscopes have a "power wash" function to direct a jet of water towards a target in the lumen. This can be very useful for cleaning debris that may coat the mucosa or obscure the lens. Angulation wires that are connected to the up-down and right-left control wheels run the length of the insertion tube. These are used to flex or even retroflex the tip of the endoscope.

The insertion tube is made from multiple layers of polymers that provide durability as well as flexibility. Spiral metal bands wound in opposite directions run through the length of the insertion tube; they transmit force and torque (twist) from the end of the tube to its tip (Fig. 3.3). Certain specialty endoscopes have devices to create variable rigidity of the insertion tube. This requires adjusting a cable that increases or decreases tension within the insertion tube (Fig. 3.4). The changes in stiffness do

## Abstract

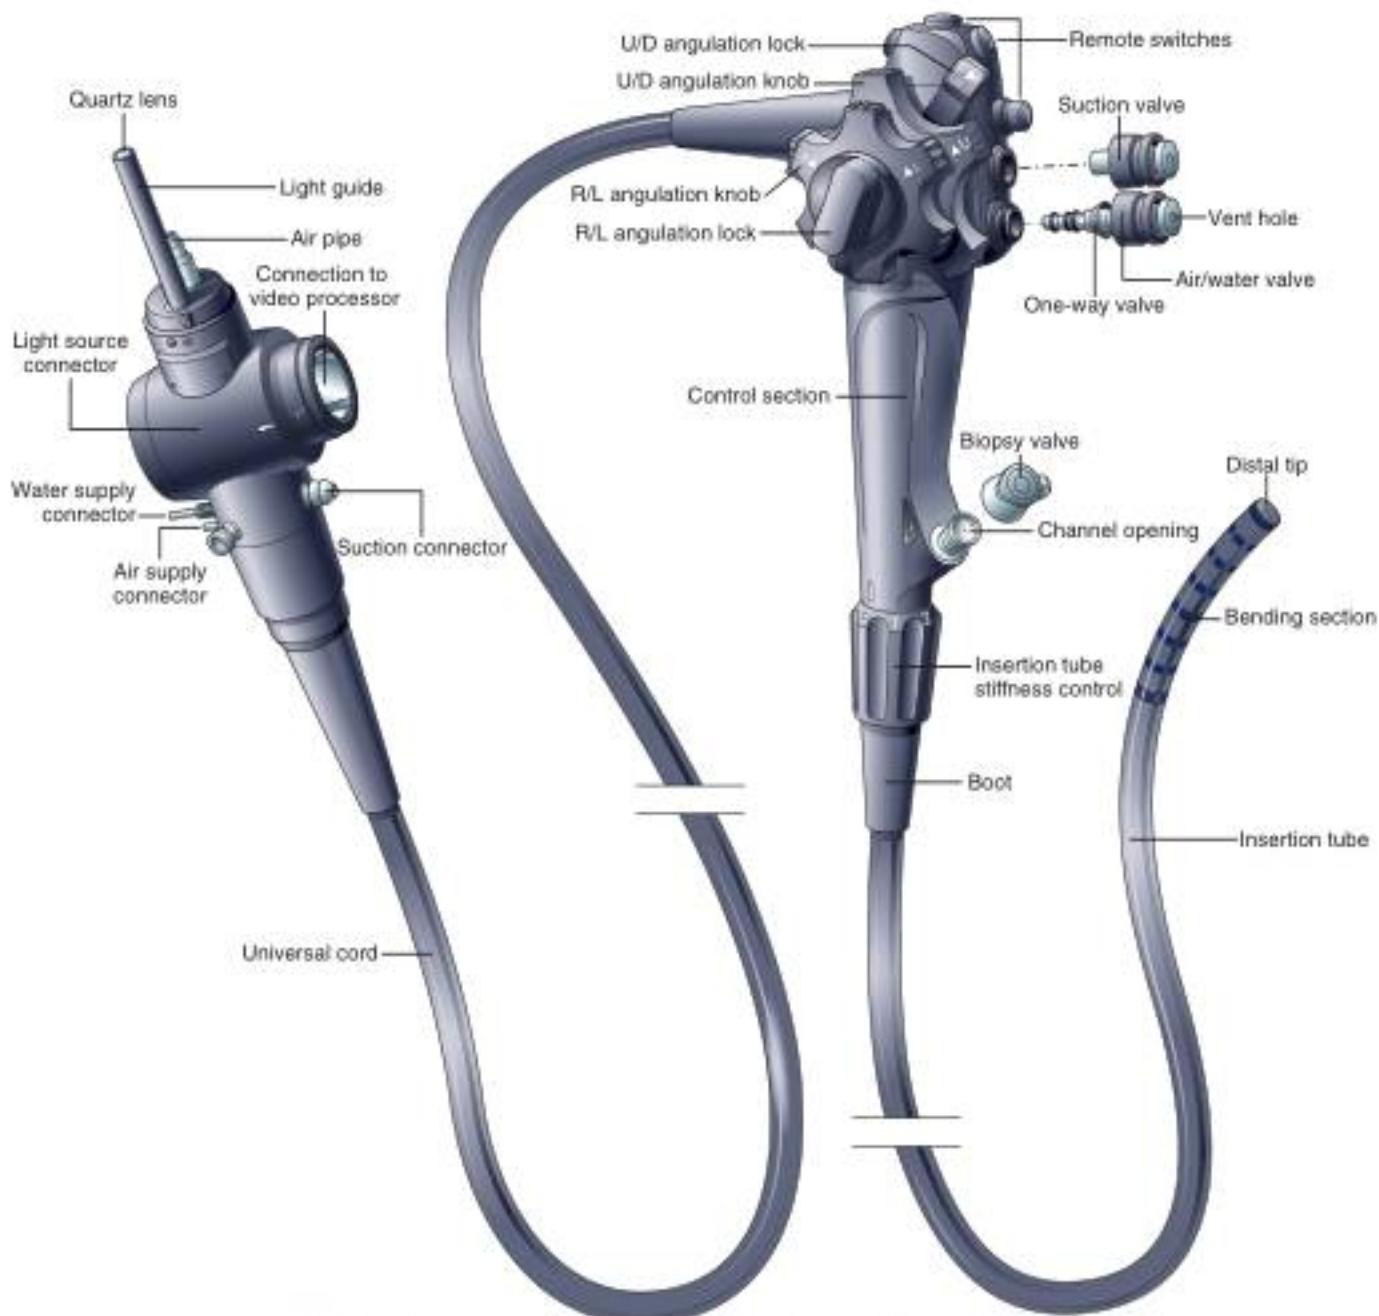

Endoscopes are flexible instruments that combine fiber-optics and charge-coupled devices to facilitate illumination and visualization of otherwise inaccessible sites, such as the lumen of hollow organs. An endoscope consists of a tip, an insertion tube and a control section. Newer endoscopes are capable of providing high-definition, high-resolution images that can be magnified to examine the mucosa in greater detail. Image-enhancing modalities can be used to selectively highlight vascular structures or enhance the appearance of the mucosa.

The most commonly used endoscopes are gastroscopes and colonoscopes, which are used for examination of the upper gastrointestinal tract and colon, respectively. Therapeutic endoscopes with larger channel diameters that allow passage of complex and sophisticated accessories are also available for advanced interventional procedures. Specialized endoscopes can be used to inspect the small bowel (enteroscopes, capsule endoscopes), biliary and pancreatic ductal systems (duodenoscopes, choledochoscopes), as well as the extra-luminal anatomy (echoendoscopes). These devices are used for a wide array of applications including assessment of the mucosa of the gastrointestinal tract, visualization and resection of polyps, management of gastrointestinal bleeding, obtaining tissue samples of extra-luminal organs, and screening for pre-malignant conditions.

This chapter describes the design and types of endoscopes, its image-processing capabilities, and the various accessories now being used in clinical practice.

## Keywords

gastrointestinal endoscopes

not extend to the distal 15 to 20 centimeters of the insertion tube, where separate inputs control the use of the so-called bending section.<sup>2</sup>

### Tip of the Endoscope

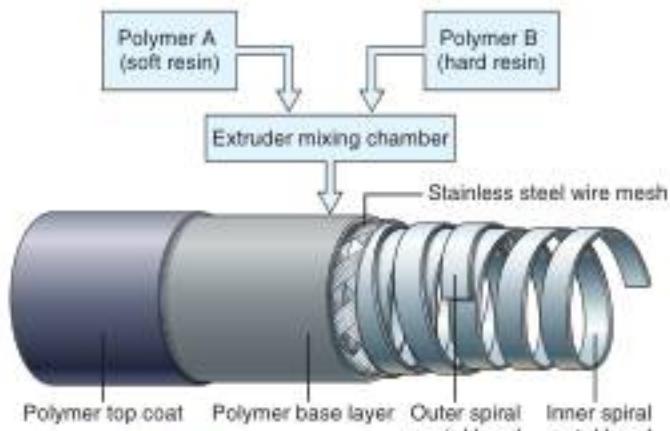

The objective lens is among the many components of the endoscope mounted on the distal end or the tip of the insertion tube. This lens may be forward-facing, oblique, or side-viewing. In close proximity of the lens lies a nozzle that directs a jet of water to clean debris off the lens. A charge-coupled device (CCD) unit connected to objective lens is mounted inside the tip (Fig. 3.5A). The CCD and the objective lens form an integrated system that allows seamless transmission

of images from the tip of the endoscope through the insertion tube directly into the processing unit through an "umbilical cord" (connector).

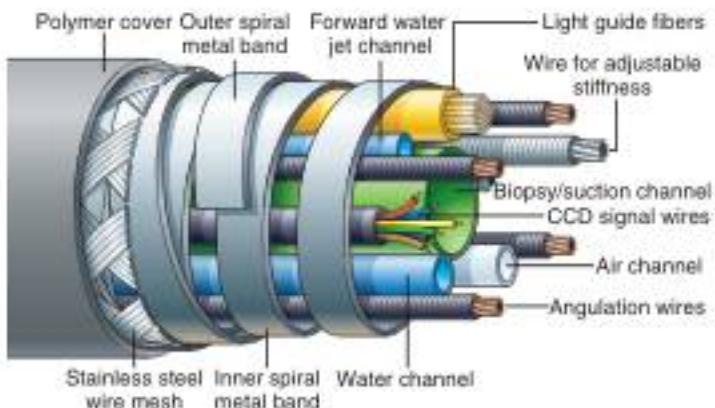

The illumination system ("light source") transmits light into the field of view. The distal tip is also a source of air and water insufflation. The largest opening in the endoscope is a port for passage of a biopsy forceps or other endoscopic accessories. The spatial orientation of the various ports and components of the endoscopes is important (see Fig. 3.5B), especially when planning complex endoscopic interventions, such as large polypectomies.<sup>3</sup> Specialized endoscopes have accessories geared towards specific purposes, such as ultrasonographic (EUS) transducers in echo-endoscopes (see later).

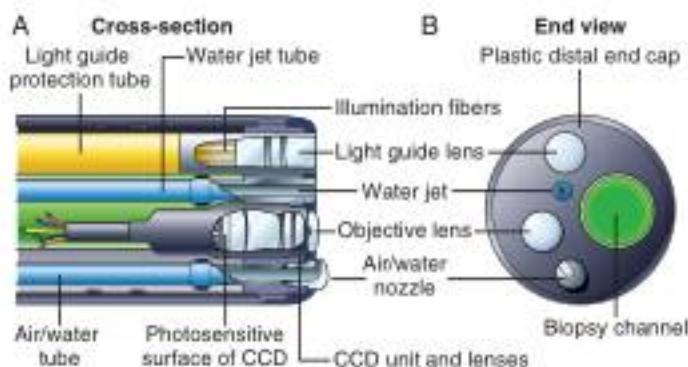

**FIG 3.2** **A** and **B**, Angulation knobs in the control section cause deflection of the tip of the endoscope.

**FIG 3.3** Layers of the insertion tube.

**FIG 3.4** Internal components of a variable-stiffness colonoscope. CCD, Charge-coupled device.

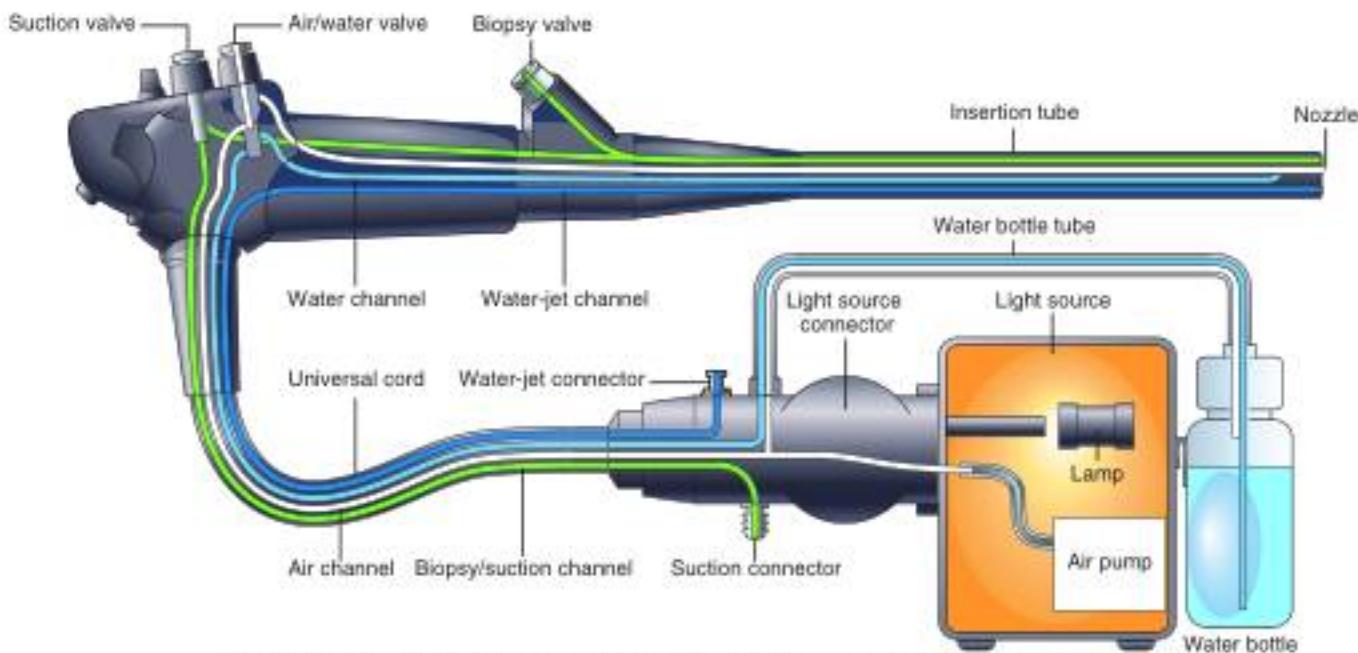

**FIG 3.5** **A**, The tip of the endoscope with internal components and **B**, their spatial orientation externally. CCD, Charge-coupled device.

The endoscope is integrated with an image processor through a connector (the umbilicus mentioned earlier). Electronic images are sent from the processor to a color monitor (TV screen). The processor also houses a powerful (usually quartz-halogen) light source, an air pump and a water bottle (Fig. 3.6). The modern endoscope is a precision tool for performing a wide range of diagnostic and therapeutic procedures.

## IMAGE PROCESSING

In the earliest iteration of the endoscope, fiber-optic imaging was used to transmit the light from the illuminated end of the endoscope to the eye piece. The fiber-optics were encased in bundles that ran the length of the endoscope and used the principle of total internal reflection of light.<sup>1</sup> These fiber-optic

**FIG 3.6** Configuration of the air, water, light, and suction systems in the endoscope.

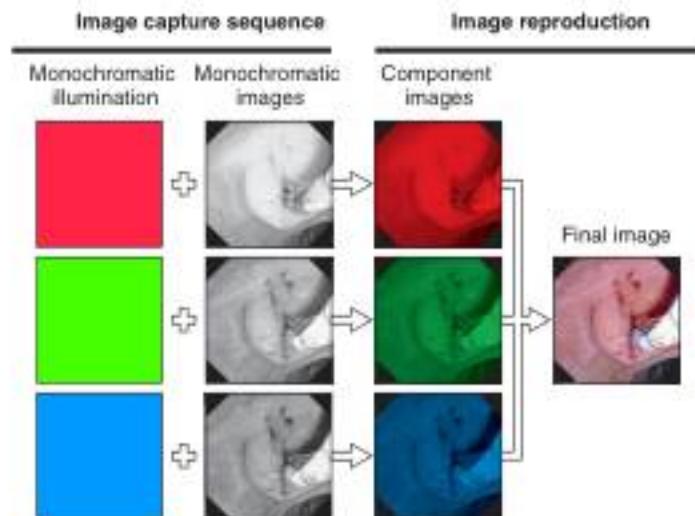

cables were susceptible to damage and the optical arrangement required the endoscopist to hold the endoscope close to the eye.

As technology progressed, CCDs came into being and heralded the era of video endoscopy, which displays images on a screen. This freed the endoscopist from the tyranny of the eye piece, enabling an ergonomically friendly procedure with a substantially lesser risk of body fluid splashes. The CCD is an integrated circuit with photocells that generate electrical charge when hit by light (photons). The amount of charge produced is proportional to the brightness of the light. The system requires the use of a bright xenon lamp to produce white light, which is then transmitted through a filter to provide illumination. The reflected light is then processed by the CCD to an image on the monitor.<sup>1</sup> Using multiple filters, a mosaic of colors can be produced, resulting in a video image. Hence, the CCD essentially converts an image into a sequence of electronic signals which, after appropriate processing, are transformed into an image on the monitor screen.<sup>1</sup>

Before current technology allowed the etching of filters directly on to a chip, a rotating wheel with primary color filters was used to synthesize the fine-color image. This system suffered from a pronounced "flicker effect". On modern CCDs, each pixel is given one of the three primary color filters (red, blue, green) by metal oxide etching. One pixel will measure the intensity of light through a red filter; adjacent pixels do the same through blue and green filters. When the values of the colors and brightness levels from the three adjacent pixels are combined in a process repeated throughout the whole CCD, a full-color video image is the result (Fig. 3.7).<sup>1</sup>

Advances in CCD design and, more recently, complementary metal oxide semiconductor technology, have resulted in smaller chips with an increased number of pixels and increased resolution.<sup>1</sup>

Along with advances in image resolution, progress has also been made in magnifying the endoscopic images. High-magnification endoscopes are defined by the capacity to perform optical zoom by using a movable lens in the tip of the endoscope.

**FIG 3.7** Capture and reproduction of a color image.

Optical zoom obtains a magnified image of the target while maintaining image display quality. This is distinguished from electronic or digital magnification, which simply enlarges the image on the display, with a consequent decreased pixel density and decreased image quality.<sup>2</sup> Certain endoscopes even employ a movable, motor-driven lens in the tip of the scope that can change the focal distance and provide a magnified view of the mucosal surface<sup>2</sup> (Video 3.1).

## TYPES OF ENDOSCOPES

Different types of endoscopes are available to examine different areas of the human GI anatomy. The most commonly used are gastroscopes used for esophagogastroduodenoscopy (EGD) and colonoscopes for examination of the colon. Specialized endoscopes

can be used to inspect the small bowel (enteroscopes), biliary and pancreatic ductal systems (duodenoscopes, choledochoscopes), as well as the extra-luminal anatomy (echoendoscopes). Therapeutic endoscopes with larger channel diameters that allow passage of complex and sophisticated accessories are also available for advanced interventional procedures.

### Gastroscopes and Sigmoidoscopes

As the name suggests, gastroscopes are used for the examination of the upper GI tract, typically to the second part of duodenum. Conventional EGD endoscopes are introduced trans-orally and can be used to examine the esophagus, stomach and the first and second parts of the duodenum. These are forward-viewing endoscopes that can be used for diagnostic and therapeutic purposes. Therapeutic EGD endoscopes with enlarged or dual working channels are available to facilitate complex interventions.<sup>7</sup> Standard diagnostic gastroscopes are regularly used to perform flexible sigmoidoscopy.<sup>8</sup>

The narrow-caliber or ultra-slim endoscopes have a diameter ranging from 4.9 to 6 mm, which enables them to be introduced trans-nasally as well as trans-orally. The trans-nasal approach permits an unsedated endoscopic examination.<sup>9</sup> These features may provide a preferable alternative in patients who may not tolerate sedation or have narrow strictures that obstruct passage of standard-caliber endoscopes.

The narrow-caliber endoscope can examine the esophagus and stomach, but may not be long enough to reach the duodenum. Although useful for diagnostic examination, the accessory channel in these endoscopes is comparatively narrow (2 mm) and often can only allow passage of a pediatric biopsy forceps and guide-wires, but not larger devices.<sup>1</sup> These endoscopes may also cause trauma to the nasal passages, leading to epistaxis and pain. Despite these limitations, multiple studies have shown that trans-nasal narrow-caliber endoscopes are safe and effective, and can be an alternative to standard-caliber endoscopes.<sup>9,10</sup> They are discussed in detail in Chapter 11.

### Enteroscopes

As described previously, gastroscopes are unable to examine the GI tract distal to the duodenum due to their length. The lack of anatomic fixation of the small intestine beyond the duodenum causes standard endoscopes to "loop," which prevents deeper intubation. These limitations are overcome by enteroscopes, which are designed for deep intubation and examination of the small intestine. Enteroscopes are forward-viewing endoscopes but are substantially longer than gastroscopes and have devices designed to assist with intubation of the jejunum and ileum. These devices can be in the form of sleeves, overtubes, or inflatable balloons.

Balloon-assisted endoscopes employ an overtube with either a single- or double-balloon system mounted at the distal end. When inflated, the balloons are intended to anchor the endoscope in position during insertion to allow for pleating of the bowel over the endoscope shaft, reducing loop formation and allowing for greater insertion depth.<sup>11</sup> With a double-balloon enteroscope apparatus, the overtube and the enteroscope have a balloon each. Once past the major duodenal papilla, the overtube balloon is inflated to maintain a stable position and the enteroscope is advanced. Subsequently, the enteroscope balloon is inflated, the overtube balloon is deflated and the overtube is advanced to the enteroscope tip. Finally, both balloons are inflated simultaneously and the entire apparatus is carefully withdrawn to pleat the small

intestine over the apparatus. Withdrawal against the anchoring straightens the scope by reducing the loops. The preceding steps are then repeated. Double-balloon endoscopy can be done either antegrade or retrograde. Its use is limited by the often long procedure time, the need for an assistant and the need for anesthesia (usually deep sedation).

A single-balloon enteroscope does not have a balloon at the tip of the enteroscope; it only employs a balloon on the overtube. The enteroscope tip, bereft of a balloon, is anchored in place by flexing its tip in an attempt to 'hook' the mucosa at a fold. A through-the-scope system (NaviAid, Pentax Medical, Montvale, NJ) uses a disposable balloon that can be passed through the working channel of an endoscope, advanced distal to the tip of the endoscope and inflated.<sup>12</sup> This inflated balloon anchors the small intestine and allows distal advancement of the scope. Balloon-assisted enteroscopes may also be useful in patients with surgical altered anatomy, such as in patients with Roux-en-Y gastric bypass where access to the excluded gastric remnant is not feasible with a standard endoscope.

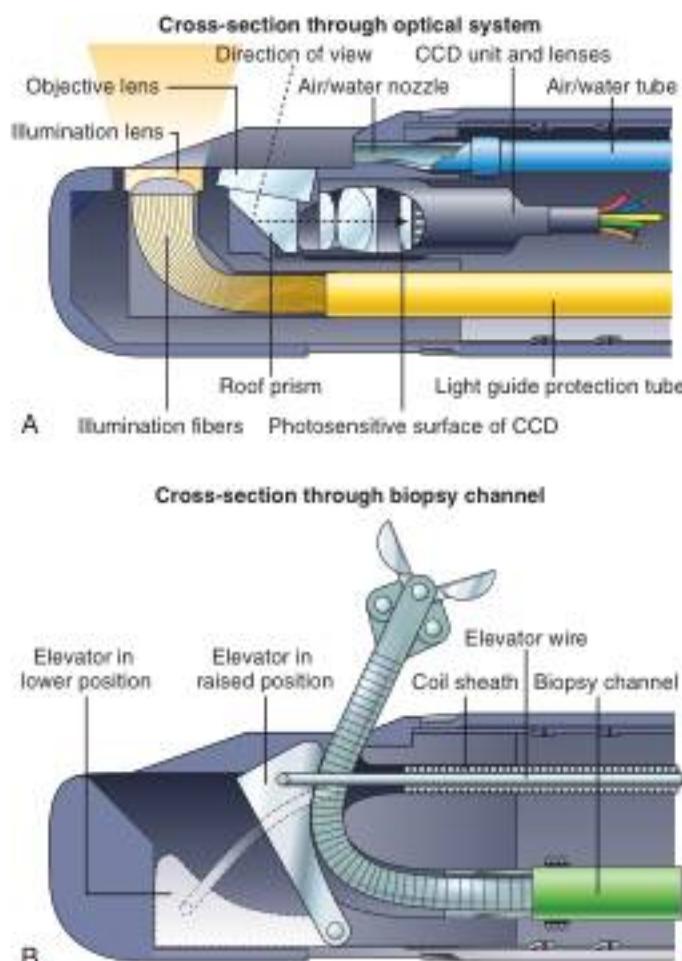

Enteroscopes that do not rely on balloons or overtubes are also available. A widely used technique called push enteroscopy can be used to examine the upper GI lumen as far as the proximal to mid-jejunum. Push enteroscopy can be performed using either adult or pediatric colonoscopes, or longer dedicated enteroscopes. These devices do not have any special accessories or overtubes but have a longer length and hence can go further into the small intestine when compared with a standard endoscope.<sup>13</sup> Spiral enteroscopes do not use balloons, but an overtube with specially designed external spirals that rotates and pleats the small intestine as the endoscope advances distally. These allow a faster advancement of the endoscope, but may have a higher complication rate.<sup>14</sup>

### Duodenoscopes

Duodenoscopes are specialized endoscopes that are used primarily for ERCP. They are side-viewing (rather than forward-viewing) endoscopes that have the advantage of looking at the major duodenal papilla en-face. Duodenoscopes have a lever that is used to manipulate an elevator located at the tip of the endoscope. By maneuvering the elevator, the endoscopist can raise and lower accessories passed through the working channel into the field of view (Fig. 3.8). Hence, they facilitate access to the bile duct and pancreatic duct, which is helpful for cannulation of the papilla. Newer accessories, such as cholangioscopes, can be passed into the biliary duct and pancreatic duct for real-time visualization and sampling of the mucosa.<sup>15</sup>

### Colonoscopes

Colonoscopes are designed for examining the entire colon and terminal ileum. Due to the flexibility of the colon where it is not tethered, there is a tendency for the colonoscope to form loops. The colonoscope is designed to minimize loop formation by varying the flexibility throughout the length of the insertion tube. The polymer covering the distal end of the insertion tube is relatively softer and more flexible to allow negotiating of angulations and curves, whereas the proximal end of the insertion tube is relatively firmer and less flexible to reduce loop formation. Certain instruments, called variable-stiffness colonoscopes, have a mechanism controlled by a dial on the proximal shaft that can be used to stiffen the proximal 40 to 50 cm of the insertion tube.<sup>16</sup> Incremental rotation of the dial adjusts the tension of a coil that runs through the insertion tube, causing the colonoscope

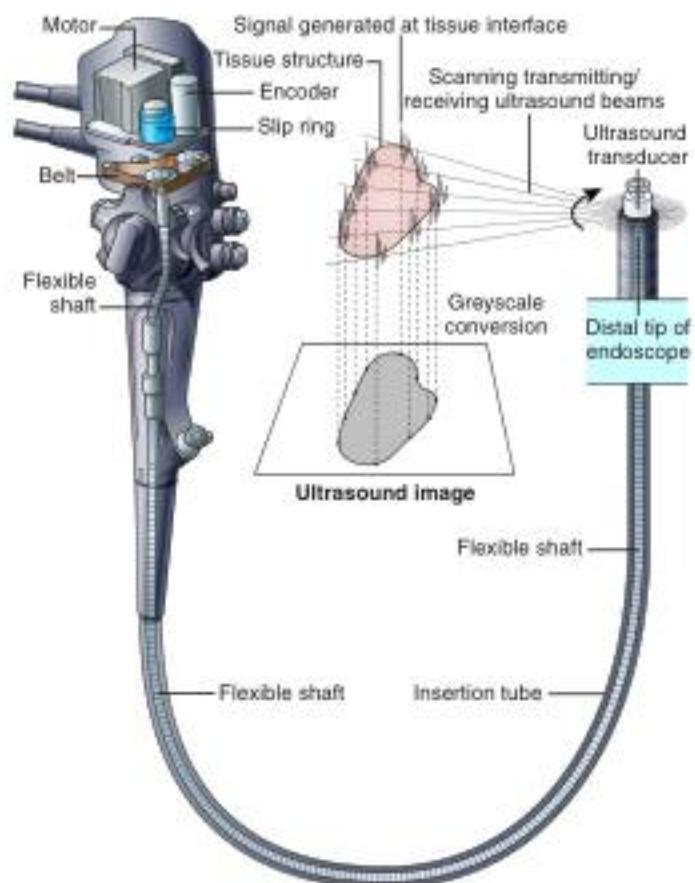

**FIG 3.8** Cross-sectional view of the side-viewing endoscope showing **A**, the direction of view, as well as **B**, use of elevator when using endoscopic accessories. *CCD*, Charge-coupled device.

to "stiffen."<sup>1</sup> Variable-stiffness colonoscopes may improve cecal intubation rates while causing less discomfort to the patient and requiring less sedation.<sup>15</sup> Over the years, colonoscopes have seen dramatic improvements in flexibility and image processing, and have become the principal method for diagnosis, treatment and follow-up of colorectal diseases.

### Echoendoscopes

Echoendoscopes differ from the standard endoscopes as they contain an ultrasound transducer at the tip, which allows for EUS examination of the GI wall, as well as extra-luminal structures (Fig. 3.9). The EUS transducer converts electrical energy into sound waves. These travel through the wall of the GI tract and impact adjacent viscera, and are subsequently reflected back to the transducer, which reconverts them into electric energy. These electric signals are processed to create an EUS image.<sup>16</sup> The transducer contains piezoelectric crystals that can scan at different sound wave frequencies. Scanning at higher frequencies enhances the resolution, but reduces depth of penetration. Hence, higher frequencies are ideal for creating sharp images of structures within or adjacent to the lumen, whereas lower frequencies are needed for the imaging of more distant structures.<sup>16</sup> Use of Doppler signal analysis allows the endoscopist to identify (and avoid) vascular structures.<sup>1</sup>

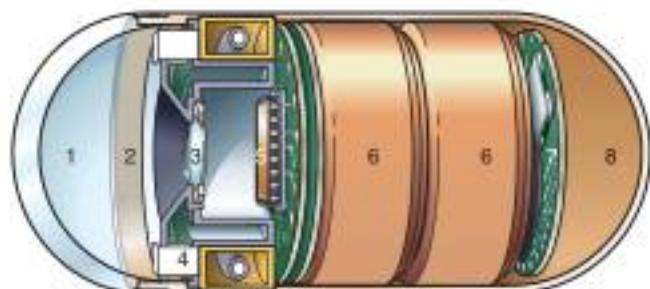

**FIG 3.9** Echoendoscope.

Echoendoscopes may be either radial or curvilinear, which refers to the orientation of the sonographic image as it relates to the axis of the insertion tube. Thus, radial echoendoscopes produce an image that is perpendicular to the insertion tube, whereas curvilinear echoendoscopes produce an image parallel to the insertion tube. The radial echoendoscope provides a 360-degree view of the anatomy, but cannot be used for interventions such as tissue sampling via a needle or a variety of therapeutic procedures. The curvilinear echoendoscope, on the other hand, visualizes structures in the 100- to 180-degree range, but simultaneously allows real-time insertion of an EUS needle.<sup>16</sup> This allows the curvilinear echoendoscope to be used in diverse interventions, such as EUS-guided tissue acquisition, direct puncture of the bile duct or pancreas to relieve obstruction, trans-enteric drainage of fluid collections (e.g., endoscopic cyst-gastrostomy), fiducial marker implantation and celiac axis neurolysis.<sup>17</sup>

### Capsule Endoscopes

Wireless capsule endoscopy is widely used in the assessment of the small bowel, especially in patients with suspected small bowel bleeding<sup>18</sup> or enteric Crohn's disease.<sup>19</sup> Recently, investigators have used this technique to evaluate more proximal pathologies, such as esophageal varices<sup>20</sup> and Barrett's esophagus.<sup>21</sup> Capsule studies have also shown encouraging results in the detection of colon polyps<sup>22</sup> and may have a role in patients with ulcerative colitis<sup>23</sup> who have had prior incomplete colonoscopies.<sup>24</sup>

The capsule itself is made of a clear plastic shell, a high-resolution CCD to capture images, a compact lens, a white

8. Antenna

**FIG 3.10** Capsule endoscope.

light-emitting diode for illumination and a battery (Fig. 3.10). The images and data are transmitted wirelessly (often via a high-frequency radio telemetry) to a sensor worn on a belt by the patient. The data from the sensor is then downloaded to a computer that has appropriate software for storage and analysis.<sup>25</sup> The software can be used to display the images in multiple or single frames. It can also identify and highlight pixels colored red to facilitate identification of bleeding lesions. The interpreting provider can review all the images at a variety of speeds, looking for mucosal lesions. It is also possible to calculate the time taken by the capsule to transit the small intestine.

The wireless capsule endoscopy typically requires a bowel preparation to clear the small intestine of partially digested food that may interfere with the visualization of the mucosa. Fasting or consuming only clear liquids 12 to 24 hours prior to the procedure is often recommended. The capsule is activated by removal from a magnetic holder and can be either swallowed by the patient, or endoscopically placed in the stomach or proximal small intestine. It is disposable and is designed to be excreted.<sup>25</sup>

Wireless capsule endoscopy may be preceded by use of a patency capsule that is made of lactose and 5% barium sulfate, and contains a radiofrequency tag. The patency capsule has the same dimensions of the capsule endoscope but can dissolve when acted upon by intestinal fluids.<sup>26</sup> The patency capsule is not required in all patients, but may be useful in those suspected to have tight strictures that could cause capsule retention and prevent further passage.<sup>27</sup>

## NEWER ENDOSCOPIC MODALITIES

### High-Definition Endoscopes

High-definition (HD) endoscopes may improve mucosal assessment and quality endpoints, such as adenoma detection rates (ADRs) for screening colonoscopy and dysplasia detection in Barrett's esophagus.

HD endoscopy uses a HD monitor (1080 lines of vertical resolution) and a high-resolution CCD with up to 1 million pixels, which provide much better images than standard video

endoscopy.<sup>28</sup> HD image displays can refresh on a line-by-line scan, which may be progressive or interlaced. Progressive scanning provides twice the temporal resolution (60 frames/sec) of interlaced scanning (30 frames/sec) and is better for video display of fast-moving objects.<sup>29</sup> A meta-analysis of five studies involving 4422 patients showed that HD endoscopes only marginally improved the polyp detection rate (incremental yield of 3.8%), as well as the ADR (incremental yield of 3.5%); this may hold especially true for flat or subtle lesions less than 5 mm in size.<sup>28</sup> Other studies have demonstrated an increase in the detection of flat and sessile polyps,<sup>29,30</sup> suggesting modest improvements in ADRs, especially for endoscopists with somewhat lower ADRs.<sup>31,32</sup>

### Digital Chromoendoscopy

The primary colors—red, green and blue—form the basis of the RGB chip used in most endoscopes. A number of commercially available systems manipulate the individual components of an endoscopic image to accentuate vascular patterns and mucosal features. This can improve the visibility of surface structures and hence the identification of GI pathology (see Video 3-1).

Narrow-band imaging (NBI) available on the Olympus platform (Olympus Corporation of the Americas, Center Valley, PA) can accentuate the vascular and mucosal features using specific filters that can, for example, enhance light absorption of hemoglobin. The basic principle of NBI is that the depth of penetration of light into the mucosa depends on its wavelength.<sup>33</sup> Deep penetration is achieved with red light, intermediate penetration with green light and only superficial penetration with blue light.<sup>34</sup> The i-SCAN technology from Pentax uses different algorithms to enhance the contrast and surface structures. For example, the surface-enhancement algorithm improves the light and dark contrast, whereas the contrast-enhancement algorithm adds blue hue to dark areas. Tone enhancement breaks and then resynthesizes the individual components of an image.<sup>35</sup> Fujinon intelligent color enhancement (FICE; Fujifilm Medical Co., Saitama, Japan) also electronically narrows the bandwidth of conventional white light colonoscopy to improve visualization using algorithms, permitting close inspection of pit patterns and microvascular structures.<sup>36</sup> Thus far, multiple meta-analyses comparing NBI and white light endoscopy have failed to show a difference in polyp detection rate or ADRs.<sup>32,33,36</sup> There are no well-designed studies that have directly compared different commercial endoscopy systems for outcomes and image quality. A randomized tandem colonoscopy trial in South Korea compared NBI, FICE and conventional white light endoscopy in 1650 patients. The study found no increase in the detection of polyps or adenomas among the three modalities.<sup>37</sup> A survey of gastroenterologists, nurses and medical students who reviewed the same images had poor interobserver agreement for the quality of endoscopic images.<sup>38</sup>

### Endoscope Modifications to Increase the Mucosal Surface Area Visualized

For endoscopists doing colonoscopies, it is of vital importance to be able to inspect the entire colonic mucosa and detect subtle lesions, such as serrated adenomas. This task is made challenging by the haustral folds in the colon. The mucosa behind colonic folds is often poorly visualized due to the inherent nature of the retrograde approach of colonic inspection. Multiple endoscopic devices are now available to increase the colonic surface area available for inspection. These devices either employ extra imaging

devices or cameras with extra wide view<sup>30</sup> to allow visualization of mucosa behind the folds, or utilize accessories that can stretch and flatten the haustral folds for more complete inspection. An example of the former approach is the Full Spectrum Endoscopy (Fuse; EndoChoice, Inc., Alpharetta, GA) system, which adds imagers on either side of the forward-facing lens of the colonoscope. The Fuse system increases the endoscopists' view from an angle of 170 degrees to 330 degrees; it employs three large, solid-state contiguous monitors for display.<sup>30</sup> In an unblinded, international, randomized tandem trial, the investigators reported a significantly lower missed adenoma rate using the Fuse system compared with the standard front-viewing colonoscope.<sup>31</sup>

In a modification of the aforementioned system, the extra wide angle view colonoscope (Olympus Corporation) uses an extra 144- to 232-degree angle, lateral-backward viewing lens in addition to a standard 140-degree angle forward-viewing lens. The views from the two cameras are merged into a single 'panoramic' view and displayed as a single image.<sup>32</sup> In a small exploratory study from Japan, investigators demonstrated the safety and efficacy of the new colonoscope.<sup>33</sup>

### Accessories That Increase the Visualized Surface Area for Examination

Multiple accessories have been developed for this purpose that can either be attached to the tip of the endoscope or passed through the working channel. Some of these accessories can be reused. These accessories can mechanically flatten or straighten the haustral folds or use imaging devices to visualize the mucosa behind the folds. The NaviAid G-EYE colonoscope (Smart Medical Systems Ltd., Ra'anana, Israel) uses a permanently integrated balloon system attached at the tip of the endoscope. In a small study on a silicone model of a colon, balloon-assisted colonoscopy had a significantly higher polyp detection rate than standard colonoscopy.<sup>34</sup> The interim results of a larger randomized trial indicate an improvement in the ADR, but final results are pending.<sup>35</sup>

A similar device is the Endocuff (Arc Medical Design Ltd., Leeds, United Kingdom), which is mounted on the distal tip of the endoscope and has multiple hinged, soft finger-like projections that can flatten the haustral folds on withdrawal.<sup>36</sup> This can be used to improve visualization and stabilization during complex polypectomy.<sup>37</sup> Randomized clinical trials have demonstrated a 14% increase in the polyp detection rate,<sup>38</sup> as well as a 14.7% increase in the ADR<sup>39</sup> using the Endocuff device. The utility of the Endocuff appears to be greater in the sigmoid colon<sup>37,38</sup> than other segments, which may be due to the tortuosity of this site.

Transparent caps attached to the tip of the colonoscope have been used in a similar fashion to flatten the haustral folds for inspection of the proximal mucosa. There have been conflicting data about the ability of cap-assisted colonoscopy to increase the ADR. A study in US veterans undergoing a screening or surveillance examination demonstrated that cap-assisted colonoscopy detected a higher number of adenomas per patient.<sup>40</sup> However, a much larger study from The Netherlands showed no difference in the ADR using cap assistance in patients undergoing a screening colonoscopy.<sup>41</sup> Both studies demonstrated a reduction in the cecal intubation time.<sup>40,41</sup> A meta-analysis of 16 randomized clinical trials of 8991 patients demonstrated that cap-assisted colonoscopy detected more polyps and reduced cecal intubation time without increasing the total colonoscopy time.<sup>42</sup> A Cochrane review that evaluated 14 randomized controlled

trials suggested a marginally improved, but statistically insignificant, cecal intubation time.<sup>43</sup> A different meta-analysis concluded that use of a transparent cap increased the detection of polyps and had a higher cecal intubation rate, while having no impact on the time to cecal intubation.<sup>44</sup>

The Third Eye Retroscope (Avantis Medical Systems, Sunnyvale, CA) works differently from the previously mentioned accessories. Instead of mechanically flattening the haustral folds, it uses a retroflexed imaging system passed through the working channel of the endoscope. The retroflexed camera is positioned beyond the mucosal folds where it works like a rear-view mirror. It visualizes the mucosa behind the haustral folds and projects the image onto part of the TV screen. This allows the endoscopist to visualize the mucosa on either side of the haustral fold.<sup>45</sup> In a non-randomized study in 249 patients, Waye et al (2010) demonstrated an increase of 13.2% in the detection of polyps and an 11% increase in number of adenomas detected using the Third Eye Retroscope over standard colonoscopy.<sup>45</sup> In a similar study, investigators detected additional polyps and adenomas on the left and right colon using the Third Eye Retroscope and further demonstrated that the ADRs improve as endoscopists gain experience with the device.<sup>46</sup> Finally, in a multicenter, randomized, tandem trial comparing the Third Eye Retroscope and standard colonoscopy, the TERRACE (effect of a retrograde-viewing device on adenoma detection rate during colonoscopy) study showed 23.2% additional adenoma detection using this accessory, but with a significantly longer withdrawal and total procedure time.<sup>47</sup>

## INTRODUCTION

The field of gastrointestinal (GI) endoscopy has expanded dramatically as new procedures, instruments, and accessories have been introduced into the medical community; more than 20 million GI endoscopies are performed annually in the United States.<sup>1,2</sup> Although GI endoscopes are used as a diagnostic and therapeutic tool for a broad spectrum of GI disorders, more health care-associated infectious outbreaks and patient exposures have been linked to contaminated endoscopes than to any other reusable medical device.<sup>3–6</sup> Failure to adhere to established reprocessing guidelines or the use of defective reprocessing equipment accounts for the majority of these cases.<sup>7–13</sup> In addition, complex endoscopes such as the duodenoscope and linear echoendoscope with elevator mechanisms can transmit bacterial infections even when reprocessing protocols are reportedly followed in accordance with manufacturer and societal guidelines.<sup>14–18</sup>

The topic of endoscope reprocessing has largely been taken for granted by many endoscopists; however, standardized cleaning and disinfection protocols have been available for some time, and, with few exceptions, changes have been gradual. This slow evolution with a high safety profile may have engendered some complacency on the part of endoscopists, to the point that many endoscopists are only vaguely aware of what goes on "behind the curtain" of the endoscope reprocessing room. Instruments are used on patients, taken away by GI nurses or other health care personnel, reprocessed, and returned ready for patient use.

As the complexity of reprocessing and recognition of its importance become a concern to the medical community and our patients, endoscopists must become more educated on these issues and thereby able to participate in informed discussions with their patients. This chapter presents a pragmatic approach to proper reprocessing of endoscopic equipment, with guidance for prevention and management of infection transmission, and includes newer sterilization and disinfection technologies.

## PRINCIPLES OF REPROCESSING

### Cleaning

Cleaning refers to removal of visible soiling, blood, protein substances, and other adherent foreign debris from surfaces, crevices, and lumens of instruments.<sup>19</sup> It is usually accomplished with mechanical action using water, detergents, and enzymatic products. Meticulous physical cleaning must always precede disinfection and sterilization procedures, because inorganic and organic materials that remain on the surfaces of instruments interfere with the effectiveness of these processes.<sup>20</sup> Mechanical cleaning alone reduces microbial counts by approximately  $10^3$  to  $10^6$  (three to six logs), equivalent to a 99.9% to 99.9999% reduction in microbial burden.<sup>19–20</sup>

### Sterilization

Sterilization is defined as the destruction or inactivation of all microorganisms. The process is operationally defined as a 12-log reduction of bacterial endospores.<sup>21</sup> Not all sterilization processes

### Abstract

Outbreaks of infection transmission due to contaminated flexible endoscopes have focused the attention of health care personnel, senior management, device manufacturers, and regulators on the need to improve the approach used to offer this valuable service. This chapter presents the principles of flexible endoscope reprocessing along with a pragmatic approach to the judicious selection and proper reprocessing of endoscopic equipment, as well as guidance for prevention and management of infection transmission inclusive of newer sterilization (e.g., hydrogen peroxide vapor) and disinfection (e.g., improved hydrogen peroxide) technologies. It also provides an outline of the Quality Systems approach that is applicable to flexible endoscope reprocessing and the need for ongoing staff competency and audits of endoscope cleaning, disinfection, and storage practices. Furthermore, the most current regulatory, expert organization, and manufacturer's recommendations are reviewed.

### Keywords

flexible endoscope reprocessing  
Carbapenem-resistant Enterobacteriaceae  
key reprocessing considerations  
channel-purge drying cabinet  
biofilm  
flexible endoscope quality systems  
reprocessing personnel  
rapid cleaning monitoring tests

are alike, however. Steam is the most extensively utilized process and is routinely monitored by the use of biologic indicators (e.g., spore test strips) to show that sterilization has been achieved. When liquid chemical germicides (LCGs) are used to eradicate all microorganisms, they can be called chemical sterilants; however, the US Food and Drug Administration (FDA) and other authorities have stated that these processes do not convey the same level of assurance as other sterilization methods.<sup>18–20</sup> Other commonly used sterilization processes include low-temperature gas such as ethylene oxide (ETO), liquid chemicals, and hydrogen peroxide gas plasma.<sup>21</sup>

### Disinfection

*Disinfection* is defined broadly as the destruction of microorganisms, except bacterial spores, on inanimate objects (e.g., medical devices such as endoscopes). Three levels of disinfection are achievable depending on the amount and kind of microbial killing involved. These levels of disinfection are as follows:

1. High-level disinfection (HLD): the destruction of all viruses, vegetative bacteria, fungi, mycobacterium, and some, but not all, bacterial spores.<sup>11,22</sup> For LCGs, HLD is operationally defined as the ability to kill  $10^6$  mycobacteria (a six-log reduction). The efficacy of HLD is dependent on several factors and includes the type and level of microbial contamination; effective precleaning of the endoscope; presence of biofilm; physical properties of the object; concentration, temperature, pH, and exposure time to the germicide; and drying after rinsing to avoid diluting the disinfectant.<sup>22</sup>
2. Intermediate-level disinfection: the destruction of all mycobacteria, vegetative bacteria, fungal spores, and some nonlipid viruses, but not bacterial spores.
3. Low-level disinfection: a process that can kill most bacteria (except mycobacteria or bacterial spores), most viruses (except some nonlipid viruses), and some fungi.

Although this categorization for disinfection levels generally remains valid, there are examples of disinfection issues with prions, viruses, mycobacteria, and protozoa that challenge these definitions.<sup>24</sup>

Antiseptics are chemicals intended to reduce or destroy microorganisms on living tissue (e.g., skin), as opposed to disinfectants, which are used on inanimate objects (e.g., medical devices such as endoscopes). The difference in the way the same chemical is used to achieve different levels of disinfection and sterilization is important for endoscopy because the contact times for sterilization with any given LCG are generally much longer (hours) than for high-level disinfection (minutes) and may be detrimental to the endoscope. The relative resistance of various microorganisms to LCGs is shown in Box 4.1.

### Spaulding Classification

More than 40 years ago, Earle H. Spaulding developed a rational approach to disinfection and sterilization of medical equipment based on the risk of infection involved with the use of these instruments.<sup>25,26</sup> The classification scheme defined these categories of medical devices and their associated level of disinfection as follows:

1. Critical: critical devices or instruments come into contact with sterile tissue or the vascular system. These devices confer a high risk for infection if they are contaminated. This category includes biopsy forceps, sphincterotomes, surgical instruments, and implants, when used in sterile anatomic locations. Reprocessing of these instruments requires sterilization.

### BOX 4.1 Descending Order of Resistance of Microorganisms to Liquid Chemical Germicides

Prions (transmissible spongiform encephalopathy agents)
Creutzfeldt-Jakob (CJD)
Variant Creutzfeldt-Jakob (vCJD)
Bacterial spores
<i>Bacillus subtilis</i>
<i>Clostridium sporogenes</i>
Mycobacteria
<i>Mycobacterium tuberculosis</i>
Nonlipid or small viruses
Poxvirus
Coxsackievirus
Rhinovirus
Fungi
<i>Trichophyton</i> spp.
<i>Cryptococcus</i> spp.
<i>Candida</i> spp.
Vegetative bacteria
<i>Pseudomonas aeruginosa</i>
<i>Salmonella choleraesuis</i>
Enterococci
Lipid or medium-sized viruses
Herpes simplex virus (HSV)
Cytomegalovirus (CMV)
Coronavirus
Hepatitis B virus (HBV)
Hepatitis C virus (HCV)
Human immunodeficiency virus (HIV)
Ebola virus

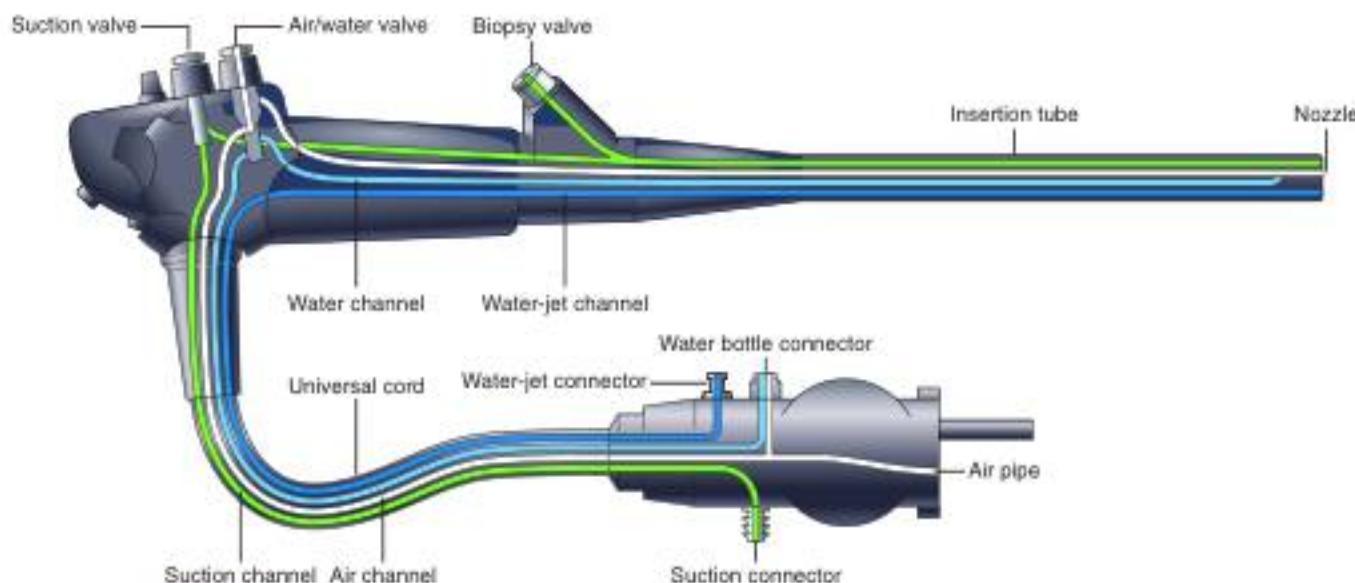

Modified from Bond WW, Ott BJ, Franke KA, et al: Effective use of liquid chemical germicides on medical devices: instrument design problems. In Block SS (ed): *Disinfection, sterilization, and preservation*, ed 4. Philadelphia, 1991, Lea & Febiger, pp 1097–1106.

2. Semicritical: semicritical devices contact intact mucous membranes and do not ordinarily penetrate sterile tissue. These instruments include endoscopes, bronchoscopes, transesophageal echocardiography probes, and anesthesia equipment. Reprocessing of these instruments requires a minimum of HLD.
3. Noncritical: noncritical devices contact intact skin (e.g., stethoscopes or blood pressure cuffs). These items should be cleaned by low-level disinfection.

## DISINFECTION AND GI ENDOSCOPY

### Endoscopes

GI endoscopes are considered semicritical devices, and the resultant minimal standard for reprocessing is HLD. This standard is endorsed by governmental agencies including the Joint Commission (JC), the Centers for Disease Control and Prevention (CDC),<sup>27</sup> and the FDA.<sup>28</sup> It is also endorsed by gastroenterology societies such as the American Society for Gastrointestinal Endoscopy (ASGE), American College of Gastroenterology (ACG), and American Gastroenterological Association (AGA), as well as medical organizations, including the Association of Perioperative Registered Nurses (AORN), Society of Gastroenterology Nurses and Associates (SGNA), Association for Professionals in Infection Control and Epidemiology (APIC), and American Society for Testing and Materials (ASTM).<sup>29–42</sup> HLD of endoscopes eliminates all viable microorganisms, but not necessarily all

**FIG 4.1** Schematic of internal channels of an endoscope. (Adapted from Olympus America. Copyright Olympus America Inc., 2003.)

bacterial spores.<sup>41</sup> Although spores are more resistant to HLD than other bacteria and viruses, they are likely to be killed when endoscopes undergo thorough manual cleaning. In addition, survival of small numbers of bacterial spores with HLD is considered acceptable because the intact mucosa of the GI tract is resistant to bacterial spore infection.

Endoscope sterilization, as opposed to HLD, is not required for "standard" GI endoscopy, as a reprocessing endpoint of sterilization has not been demonstrated to further reduce the risk of infectious pathogen transmission from endoscopes.<sup>44</sup> Sterilization of endoscopes is indicated when they are used as "critical" medical devices, such as intraoperative endoscopy when there is potential for contamination of an open surgical field.<sup>45,46</sup> In addition, individual institutional policies may dictate sterilization of duodenoscopes and linear endoscopic ultrasound instruments due to elevator mechanisms that have been difficult to clean and eradicate all bacterial contaminants with HLD alone (see the later section on Duodenoscope-Related Infections).

Despite the complex internal design (Fig. 4.1) of endoscopes, HLD is not difficult to achieve with rigorous adherence to currently accepted reprocessing guidelines.<sup>47</sup> Endoscope features that challenge the reprocessing procedures include:

- Complex endoscope design with several long, narrow internal channels and bends that make it difficult to remove all organic debris and microorganisms (e.g., elevator channel and elevator lever cavity of duodenoscopes).
- A large variety of endoscope vendors and models require different cleaning procedures and devices and materials.
- Occult damage (e.g., scratches, crevices) to the endoscope can sequester microorganisms and promote biofilm formation.

### Accessories

All valves, caps, connectors, and flushing tubes need to be adequately cleaned, rinsed, and disinfected or sterilized at the same time the patient-used endoscope is being reprocessed.<sup>48</sup> The water bottle used to provide intraprocedural flush solution and its connecting tubing should be sterilized or receive high-level

disinfection at least once daily. The water bottle should be filled with sterile water.<sup>49–52</sup> Because accessory items often do not have unique identification numbers, it is critical to ensure they are dedicated to and stored with the endoscope that they are used with. This is necessary to ensure that if there is an outbreak, it is possible to identify which accessory components were used. This may require the use of disposable accessory holders or holders such as mesh bags that are also reprocessed along with the accessories.

Most accessory instruments used during endoscopy either contact the bloodstream (e.g., biopsy forceps, snares, and sphincterotomes) or enter sterile tissue spaces (e.g., biliary tract) and are classified as critical devices. As such, these devices require sterilization.<sup>49,50</sup> These accessories may be available as disposable "single-use" or "reusable" instruments. Reuse of devices labeled *single-use only* remains controversial but has been commonly employed in many practices, primarily for economic benefits.<sup>49,51–56</sup> The FDA<sup>57</sup> considers reprocessing a used single-use device into a ready-for-patient-use device as "manufacturing," and as a result, hospitals or third-party reprocessing<sup>58,59</sup> companies that reprocess these devices are required to follow the same regulations as the original equipment manufacturers (i.e., obtain 510(k) and premarket approval application; submit adverse event reports; demonstrate sterility and integrity of the reprocessed devices; and implement detailed quality assurance monitoring protocols). This includes the development of standards and policies to determine the maximum number of uses for the devices and the training of staff in the reprocessing procedures.<sup>59–62</sup> The regulatory burden imposed by these requirements essentially eliminated the practice of the reprocessing of single-use devices by most hospitals.

### Automated Endoscope Reprocessors (AERs)

AERs were developed to replace some of the manual disinfection processes and standardize several important reprocessing steps, thereby eliminating the possibility of human error and minimizing exposure of reprocessing department personnel to chemical

sterilants.<sup>53–70</sup> AERs continuously bathe the exterior surface of the endoscope and circulate the LCG under pressure through the endoscope channels. The AER manufacturer identifies each endoscope (brand and model) that is compatible with the AER and specifies limitations of reprocessing models of endoscopes and accessories. Variations in AERs may require customization of the facility design to accommodate requirements for ventilation; water pressure, temperature, and filtration; plumbing; power delivery; and space. All models of AERs have disinfection and rinse cycles. In addition, the AERs may also have one or more of the following automated capabilities:<sup>33,69,71</sup>

1. Some AERs utilize and discard small quantities of LCG per HLD cycle, whereas others have a reservoir of LCG that is reused over multiple cycles. The latter design results in gradual dilution of the LCG and requires intermittent testing to verify maintenance of the minimum effective concentration (MEC). Product-specific test strips need to be used regularly to monitor these solutions,<sup>72</sup> which should be discarded whenever they fall below the MEC or when the use-life expires, whichever comes first.
2. The temperature and cycle length can be altered to ensure HLD or sterilization based on the LCG and type of endoscope.
3. The AER should ensure circulation of LCGs through all endoscope channels at an equal pressure with flow sensors for automated detection of channel obstruction.
4. The AER should be self-disinfecting.
5. Vapor recovery systems are available.
6. Low intensity ultrasound waves are an option.
7. Variable number of endoscopes per cycle.
8. Some AERs flush the endoscope channels with forced air or with 70% to 80% ethyl or isopropyl alcohol followed by forced air to aid in drying the endoscope channels, thereby eliminating residual water, which reduces microbial growth during storage.
9. The AER should incorporate a self-contained or external water filtration system.

LCGs and AERs must meet specified performance levels for HLD to receive FDA clearance. This is defined as a reduction in residual organic loads and a 6-log<sub>10</sub> killing of resistant indicator organisms (typically *Mycobacterium bovis*). All AERs marketed in the United States meet these criteria. The ASGE has published a summary of vendor-specific AERs and their compatible LCGs.<sup>53</sup> The FDA has approved labeling some AERs as washer-disinfectors due to the introduction of automated, brushless washing of endoscope channels prior to the disinfection cycle. Utilization of this AER washing cycle provides an extra margin of safety by providing redundancy of cleaning; however, the existing multisociety guideline<sup>53</sup> and other international standards emphasize that manual cleaning is still necessary when a washer-disinfecter is used to assure the overall efficacy of HLD.<sup>53,72</sup>

One AER (Steris System 1E [SS1E]; Steris Corp, Mentor, OH) has received FDA approval for liquid chemical sterilization, as opposed to HLD, for heat-sensitive devices that cannot be sterilized by traditional means.<sup>73</sup> This system uses filtered, ultraviolet-treated water that enters the AER and mixes with a peracetic acid-based formulation that is subsequently heated to 46°C to 55°C for liquid chemical sterilization.<sup>74</sup> This system is designed for "point of use" sterilization, as sterile storage is not possible. For flexible endoscopes processed through the SS1E, there is still a requirement for an alcohol rinse and drying prior to placing the endoscope into a storage cabinet.

The FDA also requested that AER manufacturers conduct additional validation testing to evaluate AER reprocessing

effectiveness with regard to the recess around the duodenoscope's elevator lever area.<sup>75</sup> An FDA communiqué released in February 2016 indicated that validation testing on three AER models (Advantage Plus [Medivators; Minneapolis, MN], DSD Edge [Medivators], and System IE [Steris Corp]) was complete and adequate.<sup>75</sup> In November 2015, the FDA issued a recall under consent decree for all Custom Ultrasonics (Ivyland, PA) AERs because of the company's inability to validate that their AERs were able to adequately wash and disinfect duodenoscopes to mitigate the risk of patient infection.<sup>76</sup> In a subsequent safety communication, the FDA recommended that health care facilities should not use Custom Ultrasonics System 83 Plus AERs for reprocessing duodenoscopes and should transition to alternative methods for duodenoscope reprocessing.<sup>77</sup>

### Liquid Chemical Germicides and Sterilization Technologies

LCGs have inherent limitations; however, they are universally used to reprocess flexible endoscopes and accessories due to their relative convenience, safety, and rapid action. LCGs used as HLDs should ideally have the following properties: broad antimicrobial spectrum, rapid onset of action, activity in the presence of organic material, lack of toxicity for patients and endoscopy personnel, long reuse life, low cost, odorless, ability to monitor concentration, and nondamaging to the endoscope or the environment.<sup>18,32</sup> HLD solutions can act as sterilants if an increased exposure time is used<sup>28,48,78</sup>; however, the exposure time required to achieve sterilization with most LCG solutions is far longer than is practical, and therefore these formulations are only used for HLD.<sup>48,79</sup>

The efficacy of chemical disinfectants and sterilants is dependent on their physical properties including concentration and temperature; the length of exposure of the endoscope to the chemical solutions; the type and amount of microbial debris on the endoscope; and the mechanical components of the endoscope such as channels and crevices. Because the chemicals are toxic to humans and the environment, proper handling, thorough rinsing, and appropriate disposal are essential for human safety.<sup>71</sup> When selecting a HLD product, institutional requirements need to be taken into consideration with important variables including the number of endoscopes processed per day, training requirements, turnaround time, cost information, and regulatory issues regarding safe use of the HLD products. Health care workers who use HLDs need to be familiar with and have readily accessible, product/brand-specific Material Safety Data Sheets (MSDS) and keep current with regulatory changes and new product developments.<sup>18</sup> Users should consult with manufacturers of endoscopes and AERs for compatibility before selecting an LCG. The most commonly used FDA approved LCGs for disinfection of flexible endoscopes include glutaraldehyde, ortho-phthalaldehyde (OPA), peracetic acid, and hydrogen peroxide (Table 4.1)<sup>21,30,31</sup> based chemicals in varying combinations and concentrations. Some formulations contain combinations of microbicidal agents, including glutaraldehyde and phenol/phenate, peracetic acid and hydrogen peroxide, and glutaraldehyde and isopropyl alcohol. The FDA periodically updates a list of approved HLD solutions along with some of their attributes, such as contact time and temperature required for HLD.<sup>21</sup>

Sterilization of endoscopes is indicated on occasions when they are used as critical medical devices during open surgical procedures. The risk for contamination of the operative field exists when a nonsterile endoscope enters the abdomen through

**TABLE 4.1** High-Level Disinfectants Currently Used for Endoscope Reprocessing

Agent/Action	Contact Time	Advantages	Disadvantages
<b>Glutaraldehyde</b> Biocidal activity results from its alkylation of sulphydryl, hydroxyl, carboxyl, and amino groups of microorganisms, which alters RNA, DNA, and protein synthesis.	Minimum of 45 minutes at 25°C is indicated by the manufacturers (a minimum of 20 minutes at room temperature (20°C) is adequate according to expert opinion and published guidelines)	<ul style="list-style-type: none"> <li>Long history of use in health care settings</li> <li>Excellent biocidal activity</li> <li>Relatively inexpensive</li> <li>Not corrosive to endoscopes</li> <li>Not classified as a human carcinogen</li> <li>Can be used for manual or AER systems</li> <li>Some products achieve high-level disinfection with a shorter exposure time but require a higher temperature (e.g., Rapicide, Medivators, Minneapolis, MN; IUS FDA, 2009)</li> </ul>	<ul style="list-style-type: none"> <li>Fixes proteins which allows for biofilm formation; therefore, it is critical that medical devices are thoroughly cleaned prior to exposure.</li> <li>Should not be used for reprocessing in patients with prion infection</li> <li>Reusable for 14 to 28 days (depending on formulation)</li> <li>MEC testing necessary</li> <li>Vapors are sensitizing and work areas need to be properly ventilated and air quality monitored but less than glutaraldehyde. AER mitigates this issue.</li> <li>Exposure may cause skin irritation or mucous membrane irritation (eye, nose, mouth), or pulmonary symptoms (epistaxis; asthma; rhinitis)</li> <li>Exposure may cause colitis if the endoscope is not thoroughly rinsed</li> <li>Relatively slow mycobacterial activity</li> <li>Requires inactivation or special disposal protocol</li> </ul>
<b>Orthophthalaldehyde (OPA)</b> Similar to glutaraldehyde interacts with amino acids, proteins, and microorganisms. However, OPA is a less potent cross-linking agent. This is compensated for by the lipophilic aromatic nature of OPA that is likely to assist its uptake through the outer layers of mycobacteria and gram-negative bacteria. OPA appears to kill spores by blocking the spore germination process.	Minimum of 10 minutes at room temperature (20°C); minimum of 5 minutes at 25°C (when used with an AER)	<ul style="list-style-type: none"> <li>Fast acting</li> <li>Excellent microbiocidal activity and superior mycobacterial activity compared to glutaraldehyde</li> <li>Odor not significant</li> <li>No air quality monitoring required</li> <li>Excellent materials compatibility</li> <li>Does not coagulate blood or fix tissues to surfaces</li> <li>Does not require exposure monitoring</li> <li>No carcinogen classification</li> <li>Stable in wide range pH 3-9</li> <li>In AERs, it lasts longer before reaching MEC limit (~80 cycles compared to glutaraldehyde (~40 cycles). Reusable for 14 days</li> </ul>	<ul style="list-style-type: none"> <li>An aldehyde that cross-links proteins similar to glutaraldehyde but much less active as toxicant</li> <li>Not used for reprocessing in patients with prion infection</li> <li>Stains skin, mucous membranes, clothing and environmental surfaces</li> <li>More expensive than glutaraldehyde</li> <li>Slow sporicidal activity</li> <li>May not be compatible with all AERs</li> <li>Potential irritant of eyes, skin, nose and pulmonary tree</li> <li>May require neutralization prior to disposal</li> <li>Concentrate limited use to one specific AER, and contraindicated for manual reprocessing</li> </ul>
<b>7.5% Hydrogen Peroxide</b> Produces destructive hydroxyl free radicals that can attack membrane lipids, DNA, and other essential cell components	15 to 30 minutes at 21°C (depending upon formulation)	<ul style="list-style-type: none"> <li>No activation required</li> <li>May enhance removal of organic matter and organisms</li> <li>Active against a wide range of microorganisms</li> <li>No disposal issues</li> <li>No odor or irritation issues</li> <li>Does not coagulate blood or fix tissues to surfaces</li> <li>Inactivates cryptosporidium</li> </ul>	<ul style="list-style-type: none"> <li>Material compatibility concerns (brass, zinc, copper, and nickel/silver plating) both cosmetic and functional</li> <li>Severely irritating and corrosive to eyes, skin and gastrointestinal tract if inadequately rinsed</li> <li>Excessive exposure could cause irreversible tissue damage to the eyes, including blindness. Inhalation of hydrogen peroxide vapors can be severely irritating to the nose, throat, and lungs</li> </ul>
<b>Peracetic Acid</b> Similar to other oxidizing agents it denatures proteins, disrupts cell wall permeability, and oxidizes sulphydryl and sulfur bonds in proteins, enzymes, and other metabolites	5 minutes at 30°C or 12 minutes at 50°C to 56°C depending on formulation	<ul style="list-style-type: none"> <li>Rapid sterilization cycle time (30–45 minutes)</li> <li>Low-temperature (50–55°C) liquid immersion sterilization</li> <li>Has a significantly greater efficacy at higher temperatures (e.g., a 6-log reduction of spores at 50°C in less than 2 minutes)</li> <li>Rapidly sporicidal</li> <li>Environmentally friendly byproducts (acetic acid, O<sub>2</sub>, H<sub>2</sub>O) and leaves no residue</li> <li>No adverse health effects when used under normal operating conditions</li> <li>Compatible with many materials and instruments</li> <li>Does not coagulate blood or fix tissues to protein</li> <li>Does not allow biofilm creation and has the ability to remove glutaraldehyde hardened bioburden from biopsy channels</li> <li>Has not caused resistant organisms</li> </ul>	<ul style="list-style-type: none"> <li>Potential material incompatibility (e.g., aluminum anodized coating becomes dull)</li> <li>Can corrode copper, brass, bronze, plain steel and galvanized iron</li> <li>Oxidizing ability may expose the leaks in internal channels of scopes previously disinfected with glutaraldehyde</li> <li>Considered unstable, particularly when diluted</li> <li>More expensive (endoscope repairs, operating costs, purchase costs)</li> <li>Serious eye and skin damage (concentrated solution) with contact</li> <li>Concentrates are used only in specific AER</li> </ul>

AER, automated endoscope reprocessor; FDA, Food and Drug Administration; MEC, minimum effective concentration.

**TABLE 4.2 Sterilization Technologies Used for Flexible Endoscope Reprocessing**

Agent/Action	Contact Time	Advantages	Disadvantages
Steam		<ul style="list-style-type: none"> <li>• Nontoxic to environment, staff, and patients</li> <li>• Rapid cycle time</li> <li>• Minimally affected by organic/inorganic soiling</li> <li>• Penetrates device lumens and medical packing</li> <li>• Rapidly microbicidal</li> </ul>	<ul style="list-style-type: none"> <li>• Deleterious for heat-sensitive instruments so only applicable for use with specially constructed flexible endoscopes as per MIFU</li> <li>• May leave instruments wet and susceptible to rust</li> <li>• Potential for burns</li> </ul>
Ethylene oxide (ETO)	30 minutes to 1 hour exposure depending on model of ETO sterilizer (100% ETO sterilizer versus those that use a carrier gas)	<ul style="list-style-type: none"> <li>• Penetrates device lumens</li> <li>• Compatible with most medical materials and endoscope manufacturers</li> <li>• Simple to operate and monitor</li> <li>• Sterile storage in ETO sterilization case</li> </ul>	<ul style="list-style-type: none"> <li>• Requires 8–12 hours aeration time to remove ETO residue</li> <li>• Only 20% of United States hospitals have ETO on-site</li> <li>• Long turn-around time</li> <li>• No microbicidal efficacy data proving SAL <math>10^{-6}</math> achieved</li> <li>• Studies question microbicidal activity in presence of organic matter and salt</li> <li>• ETO is toxic, a carcinogen, flammable</li> <li>• May damage endoscope</li> <li>• Requires special exposure monitoring</li> <li>• Requires special exhaust “scrubbers” to remove traces of ETO prior to release in environment</li> <li>• Requires specific ETO case to ensure adequate ETO penetration</li> </ul>
Vaporized hydrogen peroxide	~50 minutes	<ul style="list-style-type: none"> <li>• Safe for environment and no fumes</li> <li>• Leaves no toxic residue</li> <li>• No aeration necessary</li> <li>• Compatible with most devices including heat sensitive (temperatures &lt;60°C)</li> </ul>	<ul style="list-style-type: none"> <li>• Restrictions of endoscopes based on poor penetration into long and narrow lumens</li> <li>• Limited materials and comparative microbicidal efficacy data (not proven SAL <math>10^{-6}</math> achieved)</li> </ul>

MIFU: manufacturers' instructions for use; SAL: sterility assurance level.

an incision, as occurs with selected methods of intraoperative enteroscopy or postsurgical anatomy endoscopic retrograde cholangiopancreatography (ERCP).<sup>34,35</sup>

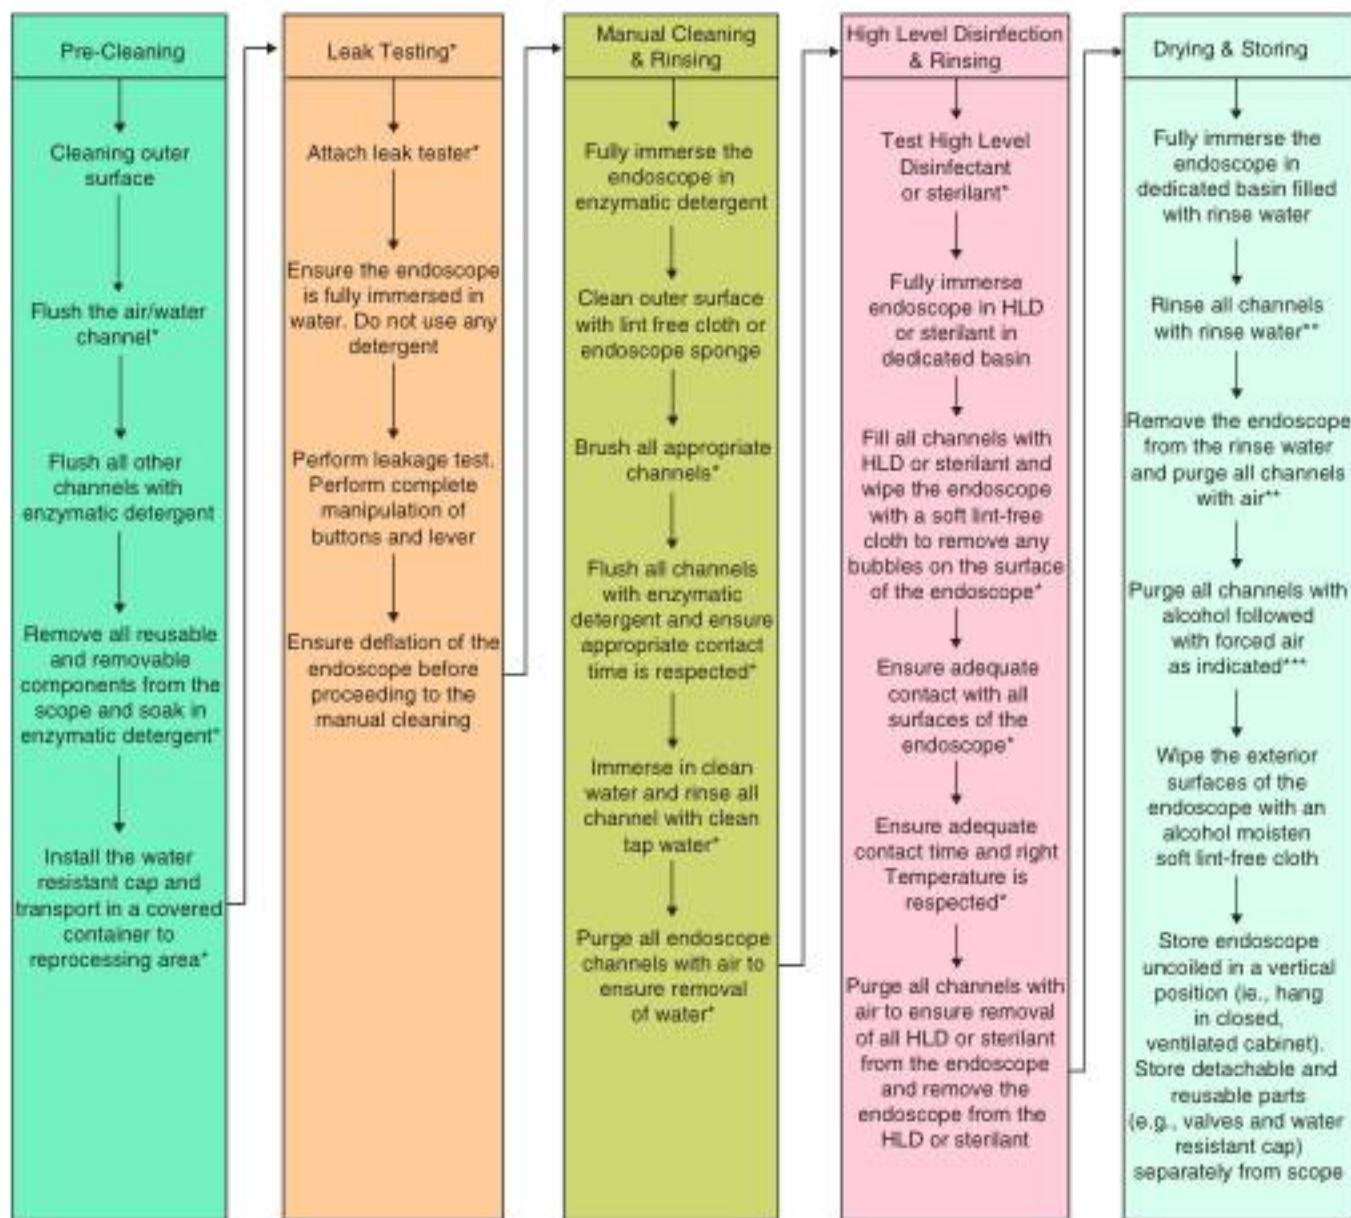

Endoscopes, when sterilized, require low-temperature methods because they are heat labile and therefore, unlike most other medical or surgical devices, they cannot undergo steam sterilization. ETO is the most commonly employed low-temperature sterilization process and a valuable method of sterilizing flexible endoscopes. However, a lengthy aeration time is required following ETO sterilization to allow desorption of all residual toxic gas from the endoscope. Additional steps must be taken, such as the application of a venting valve or the removal of the water-resistant cap to ensure proper perfusion with the gas and to prevent damage to the endoscope due to excessive pressure build-up. In addition, there are potential hazards to staff, patients, and the environment related to ETO toxicities (Table 4.2).<sup>36</sup> The International Agency for Research on Cancer has classified ETO as a known (group 1) human carcinogen. Within the past two decades, several new, low-temperature (< 60°C) sterilization systems have been developed, including hydrogen peroxide gas plasma, vaporized hydrogen peroxide, peracetic acid immersion, and ozone<sup>37–42</sup> (see Table 4.2).

## GI ENDOSCOPE REPROCESSING

Over the years there has been a continuous expansion of the diagnostic and surgical techniques being performed utilizing

ever more complex GI flexible endoscopes. The combination of ultrasonic capability with flexible endoscopes has opened up a new tool to use for the diagnosis and staging of cancers. However, along with these improvements that enhance diagnostic capabilities comes the increasing complexity of the endoscope channels. These complexities include double instrument channels with connector bridges, ultrasound probe channels, auxiliary channels, and elevator lever wire channels (sealed and unsealed). These complexities in endoscopes have far-reaching impacts in terms of reprocessing of reusable flexible endoscopes. This has been painfully highlighted by the recent outbreaks of antibiotic resistant bacteria associated with fully reprocessed endoscopes that remain contaminated<sup>15,28,30–34</sup> and act as fomites that transmit bacteria to a high percentage of subsequent patients who are exposed to the contaminated endoscope (see later section on **Infection Control Issues** for more detailed information on infection transmission). Such outbreaks have focused attention on the cleaning and disinfection of flexible endoscopes. There has been a paradigm change in that it is now recognized that reprocessing of GI flexible endoscopes is an extremely complex process that requires a quality systems approach, which includes specific training for reprocessing personnel, adequate monitoring of various stages in the reprocessing cycle, and ongoing documentation of staff competency.<sup>43–45,105–114</sup>

Human factors play a critical role in compliance with reprocessing of GI endoscopes.<sup>115</sup> Ofstead et al (2010) demonstrated that compliance with all the reprocessing steps occurred for only

\* As per manufacturer of the product

\*\* As prescribed by the manufacturer or the High Level disinfectant AND in accordance to the manufacturer of the endoscope

\*\*\* Alcohol rinse and drying is not needed if scope is used immediately on another patient, unless the final rinse was with unfiltered tap water

**FIG 4.2** Overview of the reprocessing steps for GI endoscopes. [From Public Health Agency of Canada (PHAC). Infection Prevention and Control Guideline for Flexible Gastrointestinal Endoscopy and Flexible Bronchoscopy. 2010, p 34. <http://www.phac-aspc.gc.ca/nolis-simp/guide/endo/index-eng.php>]

1.7% of flexible endoscopes reprocessed when cleaning steps were performed manually and disinfection was automated, compared to 75.4% compliance when both cleaning and disinfection were automated.<sup>15</sup> Fig. 4.2 outlines the basic steps in reprocessing of a GI flexible endoscope. Until recently, the only aspect of this process that was monitored was to test the MEC of the high-level disinfectant to ensure it contained a sufficient concentration of the active ingredient. It is easy to see from the outline provided in Fig. 4.2 how steps could be overlooked. Often staff are not aware of additional channels in new models of

endoscopes and are not trained on specific cleaning requirements. The use of different sizes and types of channel brushes for the various different channel sizes, the fact that some channels cannot be brushed, and the multitude of different types of cleaning brushes available makes duodenoscope reprocessing a confusing process prone to human error.

### Regulatory Changes

Major changes in GI endoscope reprocessing over the past five years have occurred and include new regulatory requirements,

device-reprocessing guidelines, and endoscope manufacturers' instructions for use. The key "domino" in this chain of changes was the 2015 FDA Guide to Manufacturers of Reusable Medical Devices (FDA, March 2015) that required manufacturers to validate that their cleaning instructions were effective and could achieve predetermined benchmarks. Cleaning validation for medical device reprocessing was not previously required; the focus was on validation of the disinfection or sterilization protocols recommended by manufacturers for their medical devices. When transmission of carbapenem-resistant *Enterobacteriaceae* (CRE) associated with contaminated duodenoscopes was recognized and first investigated and reported in the United States,<sup>14</sup> it was unclear why reprocessing of duodenoscopes was failing. However, it was clear that transmission rates from contaminated duodenoscopes were high (up to 45%) and that, in addition to causing infections, patients often became colonized with CRE and remained colonized long after the exposure to the CRE contaminated duodenoscope. Some health care facilities continued to report CRE transmission and suggested that the manufacturers' instructions for use (MIFUs) for endoscope reprocessing were inadequate<sup>15,163,166</sup> and that was why endoscope contamination was ongoing. Although there had been recent design changes by the three main duodenoscope manufacturers whereby the elevator wire channel was sealed, the transmission of CRE was reported for duodenoscopes with both sealed and unsealed elevator wire channels.<sup>14,15,167</sup> However, one thing was clear; it was very difficult to adequately clean the lever cavity in duodenoscopes, and visible patient debris under the elevator lever was detected in one published outbreak.<sup>168</sup> This has prompted new validated cleaning instructions for the lever cavity of duodenoscopes.<sup>169</sup> The CRE outbreaks linked to contaminated duodenoscopes prompted the FDA to convene an advisory panel meeting in May 2015, and on August 4, 2015, the FDA issued a Safety Communication<sup>170</sup> with the recommendations from the advisory panel meeting that included:

1. Establishing and implementing a comprehensive quality control program for endoscopy reprocessing to ensure meticulous adherence to MIFUs for duodenoscope reprocessing, adequate training of reprocessing personnel, and audits to ensure ongoing compliance.
2. Supplemental measures to be considered by sites offering ERCP procedures, including:
  - Microbiological culture with quarantine of contaminated endoscopes until culture results become available;
  - Meticulous cleaning and HLD followed by one of:
    - ETO sterilization,
    - Liquid chemical sterilization, or
    - Repeat HLD.

The FDA safety alert was followed by a CDC Health Advisory in September 2015, that indicated an immediate need for sites utilizing duodenoscopes to undertake audits of the reprocessing protocol, as well as staff training and longitudinal audits to document ongoing staff competency.

These events and actions have led to a "paradigm shift" regarding the reprocessing of flexible endoscopes,<sup>171</sup> whereby the need for a total quality systems approach has been recognized. It is no longer adequate to accept that endoscope cleaning is being done properly just because the MIFUs are available to staff; rather, there needs to be evidence of monitoring and ongoing audits of cleaning compliance for all staff who reprocess endoscopes. In addition, the need to ensure the endoscopes are truly dry during storage to prevent biofilm formation has been

identified.<sup>97,98,108,110,113,118-123</sup> If biofilm forms, the ability of disinfectants to reliably kill microorganisms within biofilm is dramatically reduced.<sup>118,122</sup>

## Efficacy of Reprocessing

### Overview of Quality Systems Approach

Although most published reports of infectious outbreaks related to flexible endoscopes have involved duodenoscopes, other endoscopes including colonoscopes, gastrosopes, bronchoscopes, cystoscopes, and ureteroscopes (see later sections on Reprocessing Errors and Outbreak Management and Infection Control Issues), have been shown to be contaminated and involved in infectious outbreaks. As such, every site offering flexible endoscopy procedures should ensure they have an established quality system for reprocessing these complex devices as recommended by the FDA<sup>172</sup> and CDC.<sup>123</sup> Table 4.3 provides an overview of what components are needed for such a system. As recommended by the CDC,<sup>123</sup> the first step that all health care facilities should undertake is to perform an audit by reviewing their current endoscopy services to ensure they meet all aspects of a quality system approach. This requires input from administration, risk management, endoscopy staff, and infection prevention and control to ensure that all components are adequately assessed and the appropriate policies and procedures documented and implemented.

Table 4.4 provides an overview of the key steps in reprocessing and outlines where mistakes are frequently made, as well as the impact of such mistakes. It is important that audits done for endoscope reprocessing are observational and based on a specific checklist of critical components, as well as data to substantiate processes (e.g., time data to show contact time with detergent during cleaning, as well as transport times to determine how frequently it exceeds 1 hour). Table 4.4 is a useful aid to review during initial training of staff, as well as during discussion of audit data on a yearly basis.

### Cleaning Monitoring (Rapid Testing of Organic Residuals and Adenosine Triphosphate [ATP])

The need to monitor the adequacy of cleaning<sup>173</sup> is a critical step in the Total Quality System approach (see Table 4.3) to endoscope reprocessing. Appropriate benchmarks for cleaning markers have been established.<sup>46,51,109,118,123,124-126</sup> There are a number of rapid cleaning tests (RCT) available for monitoring organic residuals such as hemoglobin, carbohydrate, and protein, as well as those that monitor ATP residuals. There are published data for some of these rapid test methods,<sup>112,125-131</sup> but when selecting a rapid cleaning monitor, it is important to request that the rapid test manufacturer provide their validation data. Review of the pros and cons of the testing method based on the validation data provided by the manufacturer is an important step when selecting the RCT. Examples of the considerations for selecting the RCT are shown in Table 4.5. Once the RCT has been selected, a way to document the RCT results is needed (e.g., a record sheet that identifies the scope tested, the person doing the testing, date and time of testing, result of testing, and the result of retesting for those scopes that fail the RCT and require recleaning).

Regardless of the method selected, the site should do initial testing for ALL endoscopes to determine the current baseline status. This should be performed on the next patient use of each endoscope after completion of manual cleaning and rinsing. If the initial RCT fails for the majority of the endoscopes, this

**TABLE 4.3 Overview of Quality System Requirements for Endoscopy Reprocessing Program**

Area	Specifics
<b>1. Records:</b> There must be documentation of all reprocessing components to ensure there is a way to link which endoscopes (and corresponding accessories) were used on which patient.	<ul style="list-style-type: none"> <li>Document which endoscope was used in the patient's medical record</li> <li>Document in the reprocessing area which personnel cleaned each endoscope, which patient the endoscope was used on, the date/time it was cleaned, and which AER (automated endoscope reprocessor) was used to disinfect the endoscope (or which sterilizer was used).</li> </ul>
<b>2. Manufacturers' instructions for use (MIFU) for all endoscopes and reprocessing equipment</b>	<ul style="list-style-type: none"> <li>Ensure the MIFU for reprocessing is available in the reprocessing area</li> <li>Create a site-specific set of instructions that are based on the MIFU but indicate specific detergent, brushes, etc. that are used for reprocessing of each make/model of endoscope used at that site</li> <li>If pump-assisted flushing is used during manual cleaning, ensure instructions for use are available</li> <li>For manual cleaning, a succinct visual "aide" consisting of a summary of the process posted above the reprocessing sink, counters, etc., is useful.</li> </ul>
<b>3. Personnel</b> <ul style="list-style-type: none"> <li>Qualifications</li> <li>Training</li> </ul>	<ul style="list-style-type: none"> <li>Personnel should have appropriate qualifications (e.g., certificate in medical device reprocessing and/or course in endoscope reprocessing)</li> <li>Formal training MUST be provided for all reprocessing staff for each specific endoscope used in the facility. This training must include risk to reprocessing personnel, measures to reduce the risk of exposure to infectious material, appropriate use of personal protective equipment (PPE), need for meticulous attention to every step in reprocessing, risk to patients of infections if reprocessing is done improperly. Training should include review of written instructions, demonstration of proper technique, observation of trainee for a defined number of endoscopes reprocessed, and sign-off regarding competency.</li> <li>Personnel files should document all qualifications and all training for each staff person.</li> <li>Ongoing competency assessment should be done every year and documented for all reprocessing personnel.</li> </ul>
<b>4. Reprocessing facilities</b>	<ul style="list-style-type: none"> <li>Physically separate from patient service areas, treatment rooms and clean storage</li> <li>Adequate sink size for flexible endoscopes</li> <li>Adequate counter space for handling endoscopes</li> <li>One-way work flow (dirty to clean)</li> <li>Cleanable work surfaces</li> <li>Adequate utilities, drains, air quality</li> <li>Eye wash</li> <li>Availability of appropriate PPE for staff</li> <li>Appropriate equipment for automation of high-level disinfection (HLD) (e.g., AER) or sterilization process</li> <li>Adequate endoscope storage facilities with restricted access</li> </ul>
<b>5. Reprocessing of endoscopes</b> (See Table 4.2 for additional information)	<ul style="list-style-type: none"> <li>Traceability of each endoscope and reusable accessories used</li> <li>Documentation of all monitoring performed for cleaning and minimum effective concentration (MEC) testing</li> <li>Timely reprocessing</li> <li>Routine cleaning and decontamination protocol for AER, flushing pump, sinks, connector tubing, endoscope storage cabinets</li> <li>Policy on disposable and reusable ancillary items (e.g., water bottles, connector tubing, etc.)</li> </ul>
<b>6. Quality assurance program</b>	<ul style="list-style-type: none"> <li>Preventative maintenance (PM) program for endoscopes, AERs, flushing pump with repair history records</li> <li>Record keeping of preventative maintenance on all equipment</li> <li>Regular audits to ensure ongoing adequacy of all stages of the program</li> </ul>
<b>7. Management/oversight</b>	<ul style="list-style-type: none"> <li>Involvement of Infection Prevention and Control (IPAC) and workplace safety in all components of the endoscopy reprocessing is crucial</li> <li>A structured management scheme with regular review of the endoscopy program that includes reprocessing considerations.</li> <li>There should be regular review and reporting of monitoring data at appropriate management meetings to identify any potential issues.</li> </ul>

indicates that there may already be build-up biofilm (BBF) in the scopes being used. Remedial action would be needed for the endoscopes, which may include a longer soak time in detergent followed by extended brushing and flushing (as per scope manufacturer's input). If the endoscope fails the RCT after the remedial action, then it should be sent to the manufacturer for further remedial action (e.g., change of channels, etc.).

### Surveillance Cultures

Another stage where monitoring of the endoscope can be done is post-HLD. A Rapid Post-Disinfection Test (RPDT) that could be completed just prior to the next patient use of the scope to confirm that the endoscope does not contain viable microorganisms would be ideal. However, there is little published data for

**TABLE 4.4 Overview of the Issues Related to Reprocessing of Flexible Endoscopes**

	<b>Key Purpose</b>	<b>Reprocessing Steps</b>	<b>Common Errors</b>	<b>Impact</b>
<b>STEP 1: Bedside Clean</b>	Critical to wipe exterior and flush ALL channels to dislodge patient debris while still fresh and not dried.  The bedside clean reduces the load of organic material and microbes for the full manual cleaning step.	<b>Patient Procedure Room:</b> Detergent or water solution (as per endoscope manufacturer's instructions) is used to: <ul style="list-style-type: none"><li>• Wipe exterior using sponge or lint-free cloth</li><li>• Suction or flush ALL channels (Note: this may require use of specific endoscope flushing adaptors as per MIFU)</li><li>• Place all accessory components in detergent or water to keep moist during transport.</li></ul>	1. Forget to wipe exterior or forget to suction or flush some channels after patient procedure.	1. Dried patient-material is harder to remove during full cleaning. 2. Increases risk of inadequate cleaning and accumulation of organic material 3. Higher level of contamination in cleaning sink; increased risk of transmission of microbes to reprocessing personnel
<b>TRANSPORT</b>	An appropriate container is needed for transport of patient-used endoscopes to prevent drying of patient-material and protect endoscope from physical damage during transit.  Target ≤ 1 hour from time of bedside clean to commencement of full manual clean.	1. Place endoscope and all accessory components in a sealed, leak-proof rigid container for transport. Keep moist during transport. 2. Ensure patient-used endoscopes can be readily differentiated from patient-ready fully reprocessed endoscopes (e.g., specific labels on exterior of the transport container and/or the endoscope) 3. Transport endoscope to reprocessing area promptly (i.e., ≤ 1 hour)	1. Container not labeled to indicate that the endoscope inside is uncleared and biohazardous 2. Transported in plastic bag instead of rigid container 3. Excessive time in transit (e.g., > 1 hour)	1. Contaminated endoscope is mistaken for a processed endoscope and used on another patient. 2. If transport container is not rigid there may be damage to endoscope during transport. 3. Excessive transport time leads to replication of microbes initiating biofilm formation
<b>STEP 2: Leak Test</b>	Ensure detection of any leaks that might allow water to enter inner scope cavity and damage light source and cause corrosion of internal components. Ensure a leaking endoscope is not used on patients as their secretions may enter damaged area and be protected from HLD and provide a reservoir for subsequent transmission to other patients.	<b>Reprocessing Room</b> <b>Maintain "Dirty to Clean" workflow</b> <b>Pressurize the endoscope:</b> <b>Leak test:</b> Manual: dry or submerged in water Automated: dry or submerged in water Observe for AT LEAST 30 seconds and manipulate the control levers to articulate the distal tip in all directions Check for bubbles if submerged in water OR: Check for a pressure drop if using the dry method of leak testing	1. Water for leak test contains detergent 2. Inadequate amount of time taken to check for bubbles 3. No articulation of the control levers 4. Failure to detect small leaks 5. Failure to decontaminate endoscope that has failed leak test before shipping for repair	1. Bubbles from leaks cannot be adequately observed when detergent bubbles are present 2. Small bubbles may go undetected and result in water damage to scope 3. Small leaks in banding section not detected without articulation to stretch the sheath 4. Risk of patient secretions containing infectious organisms getting into the damaged area and being transmitted to subsequent patients causing infection or colonization 5. Risk of transmitting infectious agents to biomedical technicians performing repair. Contamination of shipping container.
<b>STEP 3: Manual Clean &amp; Rinse</b>	Remove as much patient-derived organic material as well as microbes. This is critical to ensure the subsequent disinfection or sterilization process works effectively and can provide an adequate margin of safety.	<b>Reprocessing Room</b> 1. Dismantle reusable components such as valves, caps, flushing connectors etc. and process along with endoscope. 2. Ensure endoscope is totally immersed in detergent solution. 3. Ideally suction detergent through all channels and discard this material (not in the cleaning basin). 4. Brush all openings including suction cylinder, air/water cylinder, instrument port, and outlets on umbilical end. 5. Adequate contact time with detergent (as per detergent manufacturer's instructions) to loosen debris. 6. Rinse away detergent using tap water.	1. Reusable components not properly cleaned. 2. Performing brushing while endoscope is not immersed. 3. No suction step before brushing so all patient material from channel brushed and flushed into the detergent solution. 4. Inadequate brushing of channels due to improper brush size or confusion regarding which brush to use. 5. Inadequate contact time with detergent. 6. Many detergents are protein solutions that need to be removed before the disinfection/sterilization step.	1. Increased risk of accumulation of organic material and biofilm forming. 2. Increased risk to personnel and environment due to aerosols of infectious debris. 3. Contamination of detergent solution with high levels of patient secretions increases the risk of high levels of organic material and microbes on exterior and in channels. 4. Inadequate brushing leads to improper cleaning and risk of excessive organic and microbial load for HLD. 5. Detergent contact inadequate results in improper cleaning and leads to accumulation of organic material and microbes. 6. If detergent is not adequately rinsed away this could lead to accumulation of protein and failure of HLD.

Continued

**TABLE 4.4 Overview of the Issues Related to Reprocessing of Flexible Endoscopes—cont'd**

	<b>Key Purpose</b>	<b>Reprocessing Steps</b>	<b>Common Errors</b>	<b>Impact</b>
<b>Optional Step: Monitor manual cleaning</b>	Monitoring of the manual cleaning ensures that the endoscope does NOT go on to HLD if it has not been properly manually cleaned. ST91 recommends that all scopes be tested for adequate cleaning at least once per week and preferably daily. This process of monitoring endoscope cleaning provides evidence of a Quality System as the cleaning adequacy is documented. It also serves as an ongoing way to monitor staff compliance with cleaning as part of annual competency assessment.	<b>Reprocessing Room</b> 1. Once manual cleaning has been completed collect a sample from the channel(s) of the endoscope. Minimally a sample from the instrument port to the distal end should be collected and tested. Follow the MIFU for the rapid cleaning monitor. If the test result is below the manufacturer's cut-off for adequate cleaning, then the scope can be transferred to the AER for HLD or manual HLD done or sent for sterilization. If the test result is above the MIFU cut-off, then the endoscope needs to be fully recleaned and tested after the second manual clean. NOTE: For duodenoscopes there should also be a sample from the elevator lever recess. 2. If the endoscope fails the rapid cleaning test after three rounds of cleaning it should be sent to the endoscope manufacturer for evaluation.	1. Breach of any of the manual cleaning steps shown in Fig. 4.1 can lead to patient-derived material remaining in the endoscope that is sent for HLD or sterilization. HLD or sterilization processes fix the organic residues to the channel surface leading to build-up biofilm formation (BBF).	1. Accumulation of BBF in the endoscope increases the risk of microbes in the BBF matrix surviving HLD and possibly being transmitted to subsequent patients.
<b>STEP 4: Disinfection or Sterilization</b>	HLD and sterilization are intended to kill any remaining microbes left after the cleaning step. HLD and sterilization can achieve 6 and 12 Log <sub>10</sub> microbial reductions, respectively. All reusable accessory items must also be exposed to HLD or sterilization along with the endoscope they are dedicated to.	<b>Reprocessing Room</b> 1. Ideally an automated endoscope reprocessor (AER) should be used for HLD or sterilization. Manual HLD instructions are available from manufacturers but the manual process is fraught with concerns including ensuring adequate vapor control to prevent staff exposure to toxic fumes; adequate channel perfusion when using manual syringes to inject HLD; dilution of HLD from water remaining in channels after manual cleaning, etc. 2. When using an AER, it is necessary to change the sub-micron filter inside the AER as per MIFU. 3. Fully reprocessed endoscopes and accessory components need to be handled using clean gloves to ensure skin organisms from bare hands are not transmitted to the endoscope post-HLD.	1. Inadequate HLD contact due to poor manual perfusion of channels (e.g., bubbles or inadequate immersion). 2. Breach in sub-micron filter inside AER leads to contaminated rinse water. 3. Handling of endoscope post-HLD with un-gloved hands	1. Increased risk of microbes surviving the HLD process due to inadequate contact with HLD. 2. Microbes on the endoscope when put into storage can facilitate biofilm formation. 3. Microbes on hands transferred to disinfected endoscope can survive and subsequently be transmitted to next patient that the endoscope is used for. Microbes transferred to endoscope from hands also increase the risk of biofilm formation if there is sufficient moisture.

<b>STEP 5: Alcohol flush and forced air dry</b>	Flush all channels with alcohol and then flush with forced air. This is intended to ensure that the channels are totally dry during storage. This step can be omitted if a channel-purge storage cabinet is used (as per cabinet manufacturer's instructions). Clean gloves should be used when handling the endoscope post-HLD during the drying process.	<b>Reprocessing Room</b> 1. Through drying of endoscope exterior and ALL channels is critical prior to storage. This can be done using appropriately filtered forced air. If a "channel-purge" storage cabinet is used the manual drying only needs to be done briefly to remove excess water prior to placing the endoscope in the cabinet (ongoing air purging once the endoscope is placed in the cabinet is preferred to ensure dryness is maintained as additional wet endoscopes are sequentially placed into the storage cabinet). There are also small air-flushing pumps that can be used to ensure channel drying prior to placing the endoscope in a regular storage cabinet. Ensure adequate time is used for air-flushing to ensure scope is totally dry before being placed in a regular storage cabinet. 2. Ensure fully reprocessed endoscopes are somehow labeled or identified so they can be easily differentiated from patient-used endoscopes that are contaminated.	1. The volume of alcohol flushed and the time for manual forced air drying is not specified in MIFU and is often sub-optimal when performed manually. 2. Contaminated endoscope may be mistaken for a fully reprocessed endoscope and accidentally used on a patient.	1. Inadequate drying during storage is one of the key factors that leads to biofilm formation. Once formed, the biofilm protects microbes from being adequately killed by HLD or sterilization and increases the risk of organisms being transmitted to patients exposed to this contaminated endoscope. 2. Use of a contaminated endoscope can lead to transmission of infectious agents that result in colonization or infection.
<b>STEP 6: Storage</b>	Limited access to the clean storage room ensures the endoscopes remain microorganism free and are safe to use on the next patient. Storage for 5 to 7 days is safe providing the endoscope is stored totally dry. A method of tracking the duration of individual storage time for each endoscope is recommended so that it can be reprocessed once the 5- to 7-day storage is exceeded. Reusable valves should be dedicated to and stored alongside (but not inserted into the valve cylinders of the endoscope during storage) the endoscope they are used on. This facilitates adequate tracking of the valves associated with the endoscope if an outbreak occurs.	<b>Clean Storage Room</b> 1. Place the endoscope into the storage cabinet following MIFU. If storage cabinet is not capable of purging air through the channels – the endoscope should be hung vertically during storage. For channel-purge storage cabinets the endoscope can be stored vertically or horizontally as per MIFU. Some models alarm when scope has been stored in cabinet longer than 5 to 7 days. 2. If storage exceeds 5 to 7 days the endoscope needs to be reprocessed. 3. Store the valves and other reusable accessories in a mesh bag or disposable valve holder that is hung on the endoscope to ensure these items are dedicated to a specific endoscope.	1. Endoscope storage exceeds 5 to 7 days. 2. Staff handling the endoscopes with un-gloved hands 3. Valves are inserted into the valve cylinders during storage instead of being held in a separate mesh bag/disposable holder that is hung alongside the endoscope	1. Excessively long storage may lead to fungal or other types of overgrowth or contamination. 2. Contamination of endoscope may lead to microbial replication and biofilm formation if moisture is also present. 3. Valves inserted into the valve cylinders can lead to moisture retention that facilitates microbial replication and can lead to biofilm formation.

**TABLE 4.5 Overview of Rapid Cleaning Test Methods for Monitoring Manual Cleaning of Flexible Endoscopes**

RCT Method	Substrate Detected	Pros	Cons	Refs
1. ATP There are many manufacturers of RCT for ATP (e.g., 3M, St. Paul, MN; Ruhof, Mineola, NY; Healthmark, Fraser, MI, etc.)	ATP from residual patient secretions and from microbes*	<ul style="list-style-type: none"> <li>Rapid (&lt; 2 mins to do test) once sample is collected</li> <li>There is a sponge device to collect channel sample (faster channel sampling method than fluid flush method)</li> <li>RCT for surface and liquid testing available (i.e., can test exterior of endoscope as well as fluid used to sample channels)</li> <li>Numeric measure of relative light units (RLU) provides cut-off that is less subjective</li> </ul>	<ul style="list-style-type: none"> <li>Cost (This is affected by the testing frequency selected by the site)</li> <li>Inensitive for detection of viable bacteria (needs ~3 Log<sub>10</sub>/mL of bacteria to generate 1 RLU)</li> <li>Inability to link manufacturer's cut-off for acceptable cleaning to clinical outcomes (i.e., risk of infections or colonization)</li> </ul>	125, 128–133, 135
2. Organic Residuals There are many manufacturers of RCT for organic residuals (e.g., HealthMark, Ruhoff, STERIS (Mentor, OH), etc.)	Residual patient-derived organic material such as protein, hemoglobin, carbohydrate (RCT may test one or multiples of these organic markers)	<ul style="list-style-type: none"> <li>Rapid (&lt; 2 mins to do test) once sample is collected</li> <li>Simplistic "dip &amp; read" color change of test strip indicator pads, or test using swab for surface or channel sample, then insert swab into test reagent and assess color change</li> </ul>	Inability to link manufacturer's published cut-off for acceptable cleaning to clinical outcomes (i.e., risk of infections or colonization)	124, 127, 134, 136

\*Note: ATP is present in high levels in human cells and secretions whereas in microorganisms the level of ATP per cell is very low. Testing ATP post-cleaning is NOT a measure of how high the level of viable bacteria are, but rather it is an assessment as to whether manual cleaning has removed sufficient patient-derived material to be considered adequately cleaned.

ATP, adenosine triphosphate; RCT, rapid cleaning test.

the two RPDT tests that are currently available (Table 4.6). In the absence of validated rapid test methods, culture is the only well-studied method for detection of microbial contamination of flexible endoscopes postdisinfection/-sterilization. However, there are a number of considerations when culture is used. There have been a variety of published studies on culture results from endoscopes, but there is little data on the recovery efficiency of the various endoscope extraction methods that have been used.<sup>137</sup> If a patient-ready endoscope is extracted by flushing the channel with bacterial culture media or other harvesting fluids containing various proteins or buffers containing salt, then the endoscope requires recleaning and disinfection prior to being used on a patient. If sterile, high-quality water (i.e., reverse osmosis or deionized water) is used to flush endoscope channels, the endoscope can be dried and then still be safely used on the next patient.

## REPROCESSING PERSONNEL

### Training

Personnel who reprocess flexible endoscopes must have thorough initial training regarding the reprocessing of all makes and models of endoscopes that they will be responsible for reprocessing (see Tables 4.3 and 4.4). The training process should be documented and new staff not allowed to reprocess endoscopes on their own until they have demonstrated, under supervision, that they are competent to perform reprocessing independently. The use of rapid cleaning monitor (RCM) tests for each endoscope reprocessed during training is an excellent way to document the adequacy of the trainee's ability to perform the cleaning process. Reprocessing errors are a common underlying problem for many of the reported outbreaks.<sup>95,97,98,113</sup> The "human factors" study done by Ofstead et al (2010)<sup>113</sup> showed that inadequate cleaning of channels related to the lack of adequate channel brushing (43% of scopes) and inadequate drying (45% of scopes) prior to storage of endoscopes were the two most common breaches in

endoscope reprocessing. As outlined by recent guidelines,<sup>48,107,108,123</sup> initial training and ongoing competency assessment are critical to ensuring that staff can effectively reprocess flexible endoscopes.

### Ongoing Competency Assessment

The compliance of reprocessing personnel with endoscope reprocessing protocols should be reviewed at least annually to document ongoing competency.<sup>118</sup> It is clear from some outbreaks that despite having adequate written protocols, staff may create breaches by not following some steps in the protocol.<sup>95,98,113</sup> As such, observational audits are a useful approach to determining if staff are fully compliant in following the site protocol. If ongoing cleaning monitoring is performed, the results of these tests can be included as part of documentation of ongoing competency.

## TRANSMISSION OF PATHOGENS

Transmission of exogenous pathogens (i.e., not derived from the patient) can be categorized as "nonendoscopic," which is related to care of intravenous lines and administration of medications and anesthesia, or "endoscopic," which is related to transmission by the endoscope, water bottles, and its accessories. Outbreaks of infection have been traced to process failures, including endoscopes that are damaged or difficult to clean; AER design problems or failures such as breakdowns in AER water filtration systems; and lack of adherence to reprocessing guidelines for endoscopes and accessories. There are also data that demonstrate that all the steps associated with manual endoscope reprocessing are rarely performed and some essential steps, such as brushing all endoscope channels and adequate drying prior to storage, are frequently deficient.<sup>113</sup>

These deficient reprocessing practices can be summarized as follows:<sup>52,96,113</sup>

1. Inadequate or absent mechanical cleaning of the endoscope and channels before disinfection.

**TABLE 4.6 Overview of Post-Disinfection Test Methods for Monitoring Microbial Contamination of Flexible Endoscopes**

RCT Method	Substrate Detected	Pros	Cons	Refs
<b>Rapid Endoscope Testing Methods Post-Disinfection</b>				
1. NOW test (Commercially available; Healthmark, Fraser, MII)	Enzyme activity from any residual viable Gram negative bacteria	<ul style="list-style-type: none"> <li>Low limit of detection for Gram negative bacteria (10 CFU)</li> <li>Test result available the morning after samples collected, before scope is used on patients</li> <li>Targets key organisms of concern (i.e., Gram negatives)</li> </ul>	<ul style="list-style-type: none"> <li>Test takes 18 hrs incubation so not available for scopes used multiple times the same day</li> <li>Test is dependent on efficiency of sample collection; there may be false-negatives if low levels of bacteria are not extracted by fluid flushing sample collection method</li> <li>Cannot detect Gram positive organisms of concern (e.g., <i>S. aureus</i>, <i>Enterococcus</i>, etc.)</li> <li>Cannot determine if the Gram-negative bacteria are antibiotic resistant or not.</li> </ul>	No published data
2. Polymerase chain reaction (PCR) Research PCR protocols	Residual genetic material from microbes	<ul style="list-style-type: none"> <li>Sensitive for detection of microbial genetic material</li> <li>Quantitative detection is possible</li> </ul>	<ul style="list-style-type: none"> <li>May detect genetic material from dead microbes so need to ensure the PCR test is designed to only detect genetic material in intact microbes</li> <li>Currently there are no commercial methods for rapid PCR testing.</li> <li>Limit of detection not fully established</li> <li>Cannot determine if the bacteria detected are antibiotic-resistant or not.</li> </ul>	138
<b>Traditional Culture Method</b>				
3. Culture CDC endoscope culture protocol can be used. (Note: FDA is developing an alternative to the CDC culture protocol that is based on optimal extraction methods and optimal culture protocols.)	Detects viable microorganisms (bacteria, yeast and fungi)	<ul style="list-style-type: none"> <li>Detects viable organisms of high concern including Gram negatives and Gram positives.</li> <li>Allows assessment of whether the bacteria detected are multi-antibiotic resistant</li> <li>For outbreak investigation allows for genetic typing methods (e.g., PFGE) to help identify a point-source outbreak</li> </ul>	<ul style="list-style-type: none"> <li>Requires 48 to 72 hrs before results of culture are reported.</li> <li>During outbreak investigation, quarantine of the endoscope pending culture results is necessary.</li> <li>For routine surveillance (i.e., not an outbreak investigation) the endoscope is often not quarantined and may be used on multiple patients before culture results are available. Sites need to have a response plan in place regarding notification if culture shows organisms of concern on an endoscope that has been used on multiple patients (i.e., notify the patient, the doctor or both?)</li> </ul>	14, 15, 94, 97, 98–104, 107, 121, 125, 137–142

CDC, Centers for Disease Control; CFU, colony forming units; FDA, Food and Drug Administration; PFGE, pulsed-field gel electrophoresis.

- Delay in reprocessing.
- An inadequate disinfectant was used or used improperly at an incorrect concentration, temperature, or exposure period.
- Flawed or malfunctioning AER units or use of incorrect connectors.<sup>29,301,312</sup>
- Failure to disinfect or sterilize the irrigation bottle of the endoscope regularly.<sup>140,144</sup>
- Endoscopic accessory instruments were not sterilized.
- The endoscope and all channels were not dried adequately before storage.
- Unrecognized problems with water supply.

### Nonendoscopic Pathogen Transmission

Outbreaks of hepatitis B and C viruses have occurred due to failure to follow fundamental principles of aseptic technique and safe injection practices.<sup>145,146</sup> These included improper handling of intravenous sedation tubing, reuse of syringes and needles, and use of single-dose or single-use medical vials on multiple patients.<sup>145–149</sup>

The CDC guidelines for safe injection practices include the following recommendations:<sup>150</sup>

- Use aseptic technique when preparing and administering medications and fluids.
- A sterile, single-use, disposable needle and syringe should be used for each injection on a single patient.
- Do not administer medications from single-dose vials or use IV solutions as a common source of supply for multiple patients.
- Do not keep multidose vials in the immediate patient treatment area.
- Do not reuse a syringe to access or administer medications from a vial that may be used on multiple patients, even if the needle is changed.
- In times of critical need, medications from unopened single-dose/single-use vials can be subdivided for multiple patients. However, this should only be performed by qualified health care personnel in accordance with standards in the United States Pharmacopeia chapter on Pharmaceutical Compounding.

### Endoscopic Transmission of Pathogens

More health care-associated outbreaks and patient exposures have been linked to contaminated endoscopes than to any other reusable medical device.<sup>31,32</sup> Nevertheless, endoscopy-related transmission of infection is very low and was originally estimated to have an incidence of approximately 1 infection per 1.8 million procedures.<sup>3,17</sup> This is very likely an underestimate, as many endoscopy-related infections go unrecognized because of inadequate or nonexistent surveillance programs, the absence of clinical symptoms in many patients who are colonized, a long lag time between colonization and clinical infection, and the fact that the pathogens transmitted by endoscopy are often normal enteric flora.<sup>19</sup> Endoscope-related transmission of bacterial infection has been rare since the adoption of the current multisociety reprocessing guidelines.<sup>40,51</sup> However, recent outbreaks have occurred with duodenoscopes even when the manufacturers and societal guidelines were reportedly followed correctly (see later section on Duodenoscope-Related Infections).<sup>52</sup>

The primary concern raised by infectious outbreaks is that current reprocessing guidelines are not adequate to ensure patient safety when undergoing endoscopic procedures. Endoscopes can harbor between  $10^3$  and  $10^{12}$  enteric organisms at the completion of some patient procedures. This bioburden is reduced by cleaning (i.e., bedside precleaning followed by manual cleaning) by a factor of 2 to 6 log<sub>10</sub> and the HLD step is expected to provide a 6 log<sub>10</sub> reduction of any microbes remaining after cleaning.<sup>124,155</sup> Therefore the margin of safety associated with cleaning and HLD of GI endoscopes is low, and any deviation from proper reprocessing could lead to failure to eliminate contamination, with a possibility of subsequent patient-to-patient transmission.

Biofilms can contribute to reprocessing failure and endoscope-related infectious outbreaks.<sup>124</sup> Biofilms form in endoscope channels, in AERs, and within municipal and hospital water supplies as multilayered bacteria within exopolysaccharide. These biofilms protect the bacteria against physical (e.g., brushing, fluid flow) and chemical (e.g., disinfectant) forces, making the microorganisms more difficult to remove or completely kill by HLD.<sup>151,155</sup> There is evidence that accumulation of fixed material within endoscope channels occurs over repeated usage. Biofilms that develop in endoscopes and AERs may not be detectable by surveillance culture, as cleaning and disinfection may have destroyed bacteria within the superficial layers but not those within the deeper layers. Prompt, meticulous, manual cleaning to remove biologic material and strict adherence to reprocessing protocols is the optimal approach to reduce biofilm formation/accumulation.<sup>125-126</sup> Better biofilm removal protocols are needed to address this issue.

### What Pathogens Are of Concern?

Pathogens of concern to the GI endoscopy community and general public include *Clostridium difficile*, *Helicobacter pylori*, *Escherichia coli*, norovirus, human immunodeficiency virus (HIV), hepatitis C virus (HCV), hepatitis B virus (HBV), and multidrug resistant organisms (MDROs) such as *M. tuberculosis*, vancomycin-resistant enterococcus (VRE), methicillin-resistant *Staphylococcus aureus* (MRSA), and CRE. All these established pathogens are susceptible to currently available chemical disinfectants and sterilants.<sup>17,32</sup>

### Low Concern Organisms (LCO) versus High Concern Organisms (HCO)

Surveillance cultures of endoscopes are assessed for two general categories of microbial growth, LCO and HCO. HCO should

not be detected after HLD as these organisms commonly result in a clinically significant infection including gram-negative bacteria (e.g., *Escherichia coli*, *Klebsiella spp.*, *Shigella spp.*, *Salmonella spp.*, *Pseudomonas aeruginosa*, other *Enterobacteriaceae*) as well as *Staphylococcus aureus*, and *Enterococcus spp.*<sup>128</sup> LCO are less often associated with disease; these bacteria typically include coagulase-negative staphylococci, micrococci, diphtheroids, and *Bacillus spp.* The levels of LCO on a surveillance endoscope culture can vary depending on the reprocessing, handling, and culturing practices in a facility. Typically, fewer than 10 colony forming units (CFU) of LCO does not require intervention as this most likely represents collection process contamination rather than a significant problem with the disinfection or cleaning process.<sup>129</sup> Interpretation of culture results with 10 or greater CFU of LCO should be considered in the context of typical culture results at the facility.<sup>111</sup>

Any endoscope found to be contaminated with a HCO or unacceptable CFU of LCO should cause concern and lead to repeat endoscope reprocessing followed by post-reprocessing cultures. The endoscope should be quarantined until it has been demonstrated to be free of HCO and has an acceptable level of LCO. Positive cultures should also prompt a review of the endoscopy unit reprocessing procedures to ensure adherence to the manufacturer's reprocessing instructions and to ensure proper culture methodology. If a reprocessing breach is identified, appropriate facility personnel should be notified and corrective actions should be immediately implemented. When bacteria are persistently recovered by surveillance cultures, refer to the manufacturer's instructions<sup>111,128</sup> for evaluating the endoscope for mechanical defects and consider having the endoscope evaluated by the manufacturer. In addition, when ineffective reprocessing is suspected based on surveillance cultures, it might be helpful to review positive cultures among affected patients to determine whether transmission of relevant pathogens could have occurred.<sup>111,128</sup>

### Bacterial Infections

The vast majority of exogenously acquired endoscope-related infections have been caused by bacterial transmission. The bacteria involved have been true pathogens, which always have the potential to cause infection (e.g., *Salmonella spp.*), or opportunistic pathogens that cause infection if the microbial load is sufficient and/or host-factors are permissive (e.g., *Pseudomonas aeruginosa*). In the hierarchy of relative resistance to HLD, vegetative bacteria such as *Pseudomonas spp.* and *Salmonella spp.* are the most susceptible to disinfectants, whereas the mycobacteria are less susceptible and bacterial spores (e.g., *Bacillus subtilis* and *Clostridium difficile*) are the most difficult to eliminate (see Box 4.1). Nevertheless, as previously stated, all bacteria with the exception of a few bacterial spores are highly sensitive and eliminated by HLD. *Salmonella* is a serious primary pathogen, and *Pseudomonas* is ubiquitous in many water sources, and although both these pathogens have been associated most frequently with endoscopic transmission, they are both sensitive to multiple agents, including glutaraldehyde, and other HLDs. Transmission of bacterial pathogens from flexible endoscopes has been rare since the adoption of the current 2011 multisociety reprocessing guideline,<sup>40,120</sup> with the exception of duodenoscope-related infections (discussed later).

The most commonly reported infectious agents transmitted during GI endoscopy have been *Pseudomonas aeruginosa* (45 cases)<sup>121-125</sup> and *Salmonella spp.* (84 cases).<sup>17</sup> Isolated reports of

endoscopic transmission of other enteric bacteria include *Klebsiella spp.*,<sup>164</sup> *Enterobacter spp.*,<sup>165</sup> *Serratia spp.*,<sup>166</sup> and *Staphylococcus aureus*.<sup>164</sup> The few reports of endoscopic transmission of *Helicobacter pylori* were related to inadequate reprocessing of endoscopes and biopsy forceps.<sup>167–169</sup> Current reprocessing guidelines are shown to inactivate *Clostridium difficile* spores,<sup>170</sup> and no cases of endoscopic transmission of this infection or mycobacteria have been reported. In summary, there have not been any observed GI endoscopy-related transmission of bacterial pathogens since introduction of the currently accepted reprocessing standards with the exception of duodenoscope-related outbreaks (discussed later).

### Viral Infections

Much greater anxiety is associated with the possibility of transmission of viral infections. This anxiety is surprising because the viruses of greatest concern (HBV, HCV, and HIV) are among the easiest microorganisms destroyed with standard reprocessing.<sup>171</sup> Transmission of viral pathogens by GI endoscopy procedures is rare because these microorganisms are obligate intracellular microorganisms that cannot replicate outside living tissue. Thus, even when a flexible endoscope is contaminated with viral pathogens, the burden of virus cannot increase, as they are not capable of ex vivo replication. Enveloped viruses (e.g., HIV, HBV, HCV) die readily once dried and are more readily killed by HLD compared to nonenveloped viruses (e.g., enteroviruses, rotavirus), which can survive in dry conditions.

There has been concern about the possibility of HIV transmission by flexible GI endoscopy; however, no cases have been reported to date.<sup>171–173</sup> There is only one well-documented case of HBV transmission by GI endoscopy that occurred in the setting of inadequate endoscope reprocessing.<sup>174</sup> However, transmission of HBV is very rare or does not occur when accepted reprocessing guidelines are followed.<sup>173</sup>

### Fungi

The presence of fungi is associated with prolonged storage of flexible endoscopes. Although transmission of *Trichosporon beigelii* and *Trichosporon asahii* occurred in the 1980s,<sup>175,176</sup> there are no documented cases of fungal infections by GI endoscopy when updated reprocessing guidelines are followed.

### Parasites

A single publication in the 1970s reported circumstantial evidence of *Strongyloides stercoralis* transfer to four patients from a contaminated upper endoscope. No subsequent reports of parasite transmission by GI endoscopes have been identified.<sup>177</sup>

### Prions

Creutzfeldt Jacob Disease (CJD) and variant CJD (vCJD) are degenerative neurologic disorders transmitted by proteinaceous infectious agents called prions. All prions remain infectious for years in a dried state, and resist all routine sterilization and disinfection procedures commonly used by health care facilities.<sup>178–181</sup> CJD is confined to the central nervous system (CNS) and is transmitted by exposure to infectious tissues from the brain, pituitary, or eye, whereas tissues and secretions that come into contact with the endoscope during procedures, such as saliva, gingival tissue, intestinal tissue, feces, and blood, are considered noninfectious by the World Health Organization.<sup>178–182</sup> The CDC and other infection control experts conclude that current guidelines for cleaning and disinfecting medical devices need not

be changed to protect our patients from CJD, citing no reported cases of CJD transmission by endoscopy and the lack of exposure to high-risk CNS tissue during endoscopic procedures.<sup>17,183</sup>

vCJD is a rare but fatal condition caused by the consumption of beef contaminated with a bovine spongiform encephalopathy agent. It differs from CJD in that the mutated prion protein can be found in lymphoid tissue throughout the body, including the gut and tonsils.<sup>182,184</sup> Only three cases of vCJD have been reported in the United States, and all three patients contracted the disease elsewhere.<sup>184</sup> As vCJD is resistant to conventional disinfectants and sterilants, endoscopy should be avoided, if at all possible, in patients known to harbor this agent.<sup>17,184</sup> Endoscopes used in individuals with definite, probable, or possible vCJD should be destroyed after use or quarantined to be reused exclusively on that same individual if required.<sup>182,184</sup>

### Duodenoscope-Related Infections

Between 2012 and 2015, duodenoscopes resulted in 25 international outbreaks (at least eight in the United States) of antibiotic-resistant infections with CRE and other MDROs that sickened a reported 250 patients and resulted in 20 deaths.<sup>16,17,185–188,189–191</sup> In addition, transmission resulting in a long-term carrier state has been recognized as a risk of exposure to contaminated duodenoscopes. Long-term carriage has important clinical implications due to the development of a delayed infectious complication weeks to months later or patient-to-patient transmission of pathogens when these carriers are subsequently admitted to health care or chronic care facilities.

Investigative cultures identified persistent contamination of duodenoscopes as the cause for patient infections with MDROs in most of the outbreaks.<sup>185,188</sup> Furthermore, these duodenoscope-associated infections occurred even though the sites reported strict adherence to reprocessing procedures according to manufacturer's instructions and professional guidelines.<sup>184,185,187,188,189</sup> It is likely that MDROs are acting as a marker for ineffective reprocessing due to the complex design of duodenoscopes that have difficulty reaching crevices and channels involving the elevator mechanism where persistent colonization was identified.<sup>188,189</sup> Duodenoscopes that persistently yield positive cultures likely harbor biofilms that cannot be eradicated with standard reprocessing.<sup>189</sup>

In October 2015 the FDA and the CDC released an official health advisory alerting health care facilities to review their reprocessing procedures.<sup>191–192</sup> In response to the problems with duodenoscope reprocessing, the FDA requested all three duodenoscope manufacturers to revise and validate their reprocessing instructions with provisions for additional duodenoscope reprocessing measures.<sup>193</sup> This led to the modification of manufacturers' reprocessing protocols with a larger emphasis on precleaning and manual cleaning before HLD.<sup>11,192–194</sup> One duodenoscope manufacturer (Olympus; Center Valley, PA) subsequently modified the design of the closed elevator channel to create a tighter seal.<sup>193,198</sup>

In addition, the FDA has recommended that health care facilities performing ERCP consider employing supplemental measures for duodenoscope reprocessing when facilities have the resources to do so.<sup>110</sup> Most sites where outbreaks have occurred have chosen per procedure ETO sterilization after HLD as its primary reprocessing method, and in all reported instances, ETO has prevented further MDRO transmission.<sup>110,181</sup> However, one site reported failure to eliminate MDRO contamination of a duodenoscope after HLD and ETO.<sup>110</sup> Alternative reprocessing

methods employed have included double HLD after each procedure<sup>110,115</sup> or HLD with duodenoscope quarantine until negative culture results are obtained.<sup>15</sup> Another supplemental option for reprocessing endorsed by the FDA includes the use of a liquid chemical sterilant processing system.<sup>110,197</sup> Surveillance microbiological culturing should be considered in addition to these supplemental reprocessing measures. This involves sampling the duodenoscope channels and the distal end of the scope to identify any bacterial contamination that may be present on the scope after reprocessing.<sup>158,198</sup> It must be recognized that the sensitivity of surveillance culturing of the elevator channel, the elevator lever cavity, or other scope channels is unknown. Until there are evidence-based guidelines, individual hospitals should choose from these different options based on available information and feasibility for their medical practice. However, at a minimum, there should be an audit of all facilities offering duodenoscope procedures to ensure the site has a quality system in place and is compliant with current MIFUs and guidelines.

## REPROCESSING ERRORS AND OUTBREAK MANAGEMENT

Breaches of disinfection guidelines and device failures (e.g., endoscopes or AERs) are common in health care settings, resulting in potential patient injury or infection transmission.<sup>51</sup> The identification of such a problem may stem from the result of microbiologic surveillance cultures, an infectious outbreak within an institution or isolation of a pathogen from individuals having a recent endoscopic procedure, identification of a break in reprocessing protocol, or a visibly faulty device. Endoscopy facilities should have written policies on the roles and responsibilities within the organization to identify, report, and analyze these failures.<sup>52</sup>

### Investigation of a Reprocessing Problem or Device Failure

The investigation of a breach in reprocessing or resultant outbreak should be undertaken using a standardized approach. It should focus on the identification of factor(s) that led to the exposure and protect patients from potential adverse events. The investigation should not be punitive and not attempt to assign blame to any particular individual. Rutala et al (2007)<sup>199</sup> described a process for exposure investigation, and the ASGE has published guidelines for patient assessment and notification when there is a suspected failure in the disinfection or sterilization protocol.<sup>200</sup> These can be summarized as follows:<sup>199,200</sup>

1. Confirm that the reprocessing failure occurred and assess the duration of exposure (e.g., review sterilization methods and AER records of biological parameters).
2. Quarantine any endoscopes or associated accessories that malfunctioned or are at risk for inadequate reprocessing.
3. Do not use the devices in question, such as the endoscope or AER, until proper functioning is confirmed.
4. Prepare a list of potentially exposed patients, dates of exposure, and inadequately reprocessed or malfunctioning devices used.
5. Reporting:
  - Inform facility leadership: breaches in patient safety with serious potential infection risks should be reported to facility leadership, including infection control, risk management, public relations, legal department, and selectively to local/state public health agencies, the FDA, CDC, and the manufacturers of the involved equipment.<sup>201,202</sup> This

will help with the investigation and lead to an expeditious correction of any deficiencies that are identified.

- A user facility is not required to report a device malfunction, but it can voluntarily advise the FDA of such product problems using the voluntary MedWatch Form FDA 3500 under FDA's Safety Information and Adverse Event Reporting Program.<sup>201</sup> However, if a device failure leads to a death or serious injury, the FDA and the manufacturer must be contacted, as outlined in facility policies, by the designated individual or department at the facility.<sup>202</sup> The FDA encourages health care professionals, patients, caregivers, and consumers to submit voluntary reports of significant adverse events or product problems with medical products to MedWatch (<https://www.accessdata.fda.gov/scripts/medwatch/>), the FDA's Safety Information and Adverse Event Reporting Program
- Manufacturers are required to report to the FDA when they learn that any of their devices may have caused or contributed to a death or serious injury or when they become aware that their device has malfunctioned and would be likely to cause or contribute to a death or serious injury if the malfunction were to recur.<sup>201,202</sup>
- 6. Patient notification and counseling:<sup>200,205</sup> in instances where a breach in the reprocessing protocol or damaged equipment poses a risk to patients for adverse events, it becomes the institution's ethical obligation to notify patients in a timely manner. Notification may be accomplished by a direct meeting, telephone call, and letter sent by registered mail. The content should include an assessment of the risk, possible adverse events that may occur, symptoms and signs of the adverse event, time range for the adverse event, risk to other contacts, possible prophylactic therapy (including benefits and risks), and recommended medical follow-up. Prompt notification allows patients to take precautions to minimize the risk of transmitting infection to others and allows for early serologic testing. This may help distinguish chronic infections from those potentially acquired at the time of endoscopy and to permit earlier initiation of treatment for newly acquired infections. On the other hand, adverse publicity associated with the reporting of a reprocessing error might lead patients to avoid potentially life-saving endoscopic procedures because of an unwarranted fear of infection.
- 7. Develop a long-term follow-up plan (e.g., long-term surveillance, changes in current policies and procedures) and prepare an after action report.

### Infection Control Issues

There are risks related to infection transmission to personnel who handle patient-used endoscopes as well as to patients. Sites offering endoscopy procedures need to ensure the risk to personnel and patients is minimized.

### Transporting Instruments

Flexible GI endoscopes are expensive and easily damaged. Unlike surgical instruments where the microbial load is less than 100

bacteria for 75% of instruments,<sup>139,184</sup> the load of microorganisms in channels of flexible endoscopes can be as high as  $10^{10}$  bacteria<sup>134</sup> per instrument channel (e.g., for colonoscopes). During transport from the procedure room to the reprocessing area,<sup>48</sup> flexible GI endoscopes require a rigid, sealed container that is appropriately labeled as biohazardous. This protects the endoscope from accidental damage and also ensures that any patient-derived secretions and microorganisms are adequately contained and cannot drip out and contaminate the environment. All reusable accessory items (valves, flushing adaptors, cleaning valves, etc.) should be transported along with the associated endoscope. During transport, the endoscope and all accessory items should be kept moist to prevent drying of patient-derived material. If endoscopes are transported to a central reprocessing facility, evaluation of the time of transport should be conducted to determine the frequency of excessive transit times.

### Personal Protection

There are risks to reprocessing personnel being exposed to patient-derived infectious materials. Endoscopes contacting the GI tract can have very high levels of infectious organisms (including bacteria, viruses, fungi, etc.) in channels or on the endoscope surface. To mitigate these risks, reprocessing personnel need to be trained regarding standard precautions, personal protective equipment (PPE), hand hygiene, disposal of sharps, and dealing with chemical and/or infectious material spills.

Standard precautions are required when reprocessing any patient-used medical device. This means that staff treat all patient-used endoscopes as potentially infectious regardless of the underlying known illnesses that patients might have (e.g., *Clostridium difficile* infection, VRE colonization, human papilloma virus infection, candidiasis, etc.). Any handling of GI endoscopes should be done with due consideration to the potential to transmit infectious microorganisms to reprocessing personnel. Staff must be trained in appropriate PPE and reprocessing considerations aimed at reducing the generation of aerosols.

It is critical that appropriate PPE be available<sup>48,107,184</sup> and include a gown (preferably a water-resistant gown), gloves (appropriate to the task), and a face shield/mask. Reprocessing personnel must be adequately trained in the proper donning and doffing of all PPE. Gowns, gloves, and a full-face shield (or combined face shield/mask) are required for cleaning of flexible endoscopes. The reprocessing staff needs to be trained in the appropriate use of protective gloves, as well as hand hygiene after removing gloves. Utility gloves used for cleaning of endoscopes should never be used at other stages in endoscope reprocessing (i.e., they are dedicated to the cleaning sinks). Disposable examination gloves must be available for handling cleaned endoscopes during connection to the AER. Fresh disposable gloves are needed for removing and handling fully reprocessed endoscopes from the AER and during manual channel drying and placing the endoscope into the clean storage cabinet. Fresh disposable gloves should also be used whenever an endoscope is removed from the clean storage cabinet. The use of gloves helps protect both the reprocessing personnel from contamination with patient-derived microorganisms and the fully reprocessed endoscope from contamination with skin-derived microorganisms from reprocessing personnel. Staff should always perform hand hygiene immediately after removing any type of glove. Handwashing sinks with appropriate soap, as well as waterless hand hygiene agent dispensers, must be available in the reprocessing area.

The workflow should proceed from "dirtiest to cleanest" in the reprocessing area, and there should be physical separation of "dirty" reprocessing areas and "clean" areas.<sup>48,107,184</sup> This requires appropriate removal of PPE and hand hygiene when leaving the dirty reprocessing area to enter any of the clean areas.

Staff should take every precaution to reduce the generation of aerosols during reprocessing of GI endoscopes. This includes total immersion of the endoscope during cleaning.<sup>48,107</sup> This ensures that any patient material removed from the channels during cleaning is contained within the detergent cleaning solution. Care is needed to ensure all brushing steps are done underneath the water surface to reduce aerosols. Holding the control head above water to insert the channel brush and then pulling the brush out of the channel while the control head is above the water generates significant aerosols of the contaminated detergent solution. In addition, during the air-flushing process after cleaning is completed, a piece of gauze should be placed over the distal end of the endoscope channel prior to placing it in an AER to prevent creation of aerosols when flushing out residual rinse water. A final, often overlooked step, is rinsing and decontamination of the sink after EACH endoscope is cleaned. This ensures that the sink does not accumulate microbial contamination over time and act as a reservoir within the reprocessing area to contaminate reprocessing personnel or other endoscopes. If flushing pumps are used as part of the manual cleaning step, they also require routine (usually daily) decontamination as per MIFU to ensure they do not become a reservoir of microbes that develop biofilm and subsequently contaminate endoscopes that they are used on.

Any single-use disposable sharps used in the procedure room should be disposed of in appropriate sharps containers in the procedure room. There should be no single-use disposable sharps transported to the reprocessing area. If there are reusable sharps (e.g., biopsy forceps) used for patient procedures, these should be appropriately transported to the reprocessing area in a labeled, rigid, sealed container that ensures separation from the endoscope. This reduces the risk that the biopsy forceps (or other sharp accessory device) could damage the endoscope during transit. Reprocessing of reusable sharps requires specific MIFU and adequate staff training to reduce the risk of sharps injuries to reprocessing personnel. Single-use, disposable accessories are preferred to eliminate the risks associated with reprocessing of reusable sharps.

## ENDOSCOPIC BIOPSY

### Biopsy Techniques

#### Pinch Biopsy Forceps

The most common pinch biopsy forceps used worldwide fits through a 2.8-mm biopsy channel (Fig. 5.1). In general, mucosal samples vary from 4 to 8 mm in size.<sup>1,2</sup> A smaller-sized forcep that fits through a 2.2 mm biopsy channel is used in infants and young children. Pediatric gastroenterologists generally use narrow-bore instruments for routine diagnostic biopsies if the child weighs less than 10 kg. The primary aim of a pinch biopsy is to obtain a specimen sample that contains full-thickness mucosa, including muscularis mucosa. The tissue yield of endoscopic biopsies relies on the forceps size, amount of pressure applied on the forceps while placed against the mucosa during the biopsy procedure, and the optimal angle of the forceps when applied to the mucosal surface. In the gastric body, where mucosal folds are thick,<sup>3</sup> or in conditions associated with mucosal thickening, full-thickness mucosal sampling may not be achieved using a 2.8 mm channel biopsy. The inability to sample full-thickness mucosa may influence the amount of diagnostic information obtained from histologic examination.

#### Larger Capacity Forceps

The large-cup ("jumbo" or "max capacity") forceps requires a large channel (also termed *therapeutic*) endoscope (biopsy channel; 3.6 to 3.7 mm). Some newer designs are intended to provide larger biopsy specimens with the conventional 2.8-mm channels and intermediate-sized channels such as pediatric colonoscopes. Larger capacity forceps biopsies increase the diagnostic yield upon histologic examination. Specimens obtained with a jumbo forceps often exceed 6 mm in maximum diameter, but these are not necessarily deeper than standard biopsies.<sup>4</sup> Rather, a jumbo forceps typically provides more mucosa for analysis. This is particularly useful during surveillance tissue sampling, such as in patients with Barrett's esophagus (BE) or ulcerative colitis.<sup>5</sup> Another advantage of large capacity forceps biopsies is that larger tissue fragments enable histotechnologists to better orient the sample during tissue processing. Jumbo biopsy forceps are as

safe as standard biopsy forceps, although the need to use a larger diameter channel may be less comfortable for patients.

#### Sampling of Submucosa

Biopsy specimens obtained with small or larger capacity pinch forceps usually contain very little submucosa, if any.<sup>6</sup> It is sometimes difficult to obtain specimens with sufficient submucosa, such as during a biopsy for a submucosal lesion or when the objective is to diagnose amyloid or other disorders that manifest predominantly in the submucosa. Ancillary techniques, such as fine-needle aspiration or needle core biopsy, may increase the diagnostic yield of submucosal tissue.

#### Hot Biopsy

Hot biopsy forceps are insulated pinch biopsy forceps through which electrical current is passed, after which the remaining tissue is ablated *in situ* using electrocautery.<sup>7</sup> Unfortunately, the result is cautery artifact in the sampled tissue, which, in small tissue samples, often makes histologic interpretation difficult (or impossible).<sup>8,9</sup> In addition, the electrocautery technique carries an excessive risk of perforation from deep tissue burn, particularly in the cecum and ascending colon.<sup>10,11</sup> Finally, residual dysplastic tissue on follow-up after hot forceps biopsy has been reported in 10.8% to 17% of patients post hot forceps biopsy.<sup>12,13</sup> For these reasons, hot biopsies have been largely abandoned by most endoscopists.

#### Snare Biopsy

Snare biopsy is an endoscopic technique during which a wire is placed around a polypoid lesion that protrudes into the lumen, and this allows for removal of the lesion. Snare biopsy is used primarily for colonic polyps, but polyps anywhere in the gastrointestinal (GI) tract may be removed using this technique. Snares are available in a variety of sizes and can be used in conjunction with electrocautery. Depending on their size, excised polyps are either retrieved through the suction channel of the endoscope or held by the snare after resection while the colonoscope is removed from the patient. The snare biopsy can be used to remove pedunculated or sessile polyps of various sizes.

**Abstract**

The endoscopic mucosal biopsy is an essential component for the diagnosis and treatment of numerous gastrointestinal diseases. Tissue specimens must be obtained and handled appropriately to ensure optimal histologic examination. Communication between the endoscopist and pathologist facilitates effective tissue collection and allows for efficient and accurate pathologic diagnosis. In this chapter, we discuss factors which influence this process: endoscopic sampling techniques, tissue fixation and processing, and disease specific approaches to maximize the diagnostic yield of mucosal biopsies.

**Keywords**

endoscopic biopsy  
tissue fixation and processing  
histologic examination  
disease specific appropriate tissue sampling

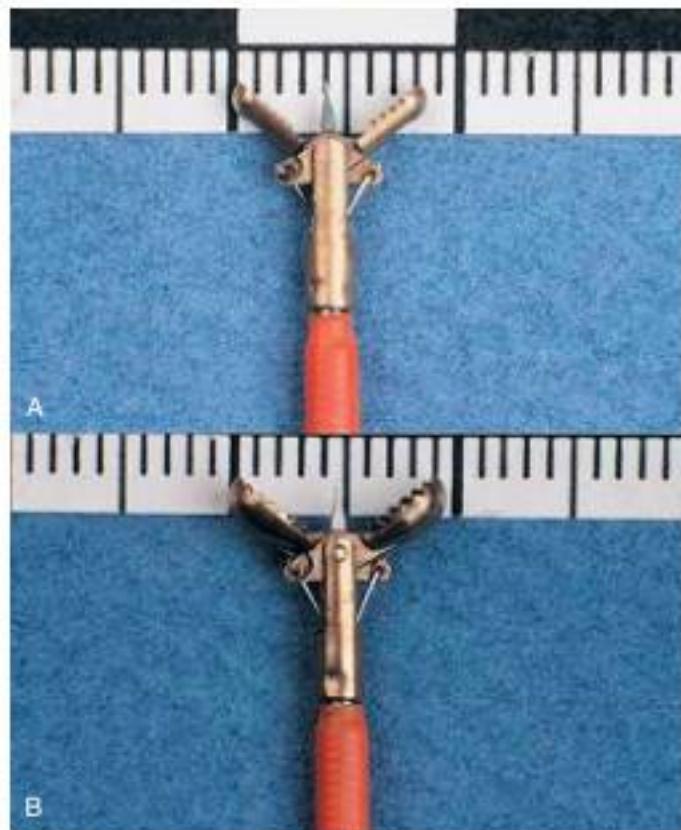

Snare biopsy is the recommended method over pinch forceps biopsy for removal of diminutive (less than 0.5 cm) and small polyps (0.5 to 2 cm). Several randomized studies have shown a higher rate of complete resection of adenomatous polyps using cold snare biopsy compared to cold forceps biopsy.<sup>14-16</sup> Pedunculated polyps are generally easily removed using snare biopsy,

and the main risk of this procedure is post-polypectomy bleeding from vessels located within the stalk of the polyp.<sup>17</sup> In the case of larger polyps, piecemeal removal may be employed.<sup>18</sup> However, piecemeal polyp removal may limit the ability of pathologists to assess the margins of resection. Sessile polyps, or complex polyps greater than 2 cm in size, are best referred to experienced endoscopy centers for removal.

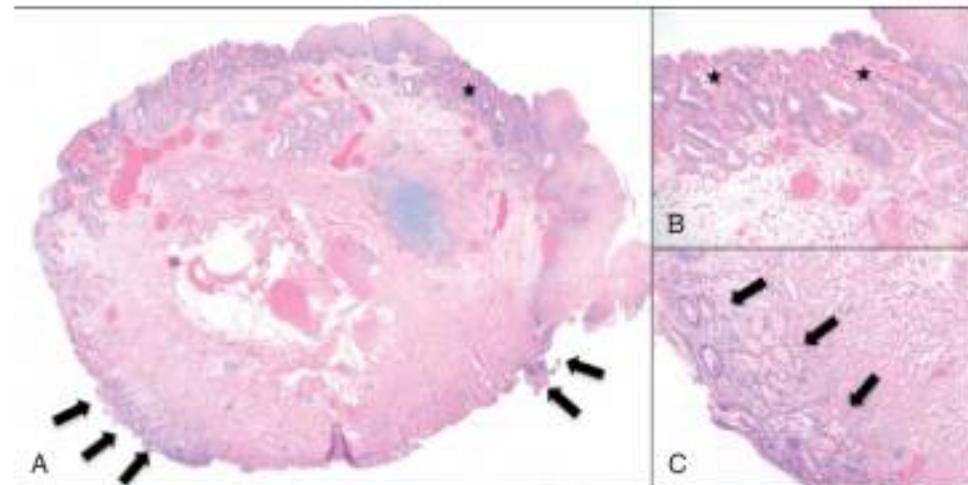

During hot snare polypectomy, the endoscopist is able to apply modulated electrosurgical current to a metal wire that cuts through pedunculated polyps at the base of the lesion. This assists tissue removal and coagulation of vessels at the base of the polyp or within the polyp stalk. Use of electrocautery versus cold snare polypectomy must be balanced against the risks of perforation and post-polypectomy bleeding. Electrocautery artifact also persists in the biopsy sample during tissue processing and is characterized by loss of nuclear and cytoplasmic detail (Fig. 5.2). Noting this effect during histologic examination can be advantageous in certain situations, such as assessment of the cauterized margin of resection. However, too much electrocautery artifact can also preclude assessment and classification of polyps, especially if the artifact is present throughout the tissue submitted for histologic examination. In general, the risk of perforation following polypectomy is minimal, and is greatest in portions of the colon covered by free serosa. Cold polypectomy, without electrical current, avoids use of cautery, thereby limiting the amount of burn artifact in the specimen and thus minimizing the risk of perforation.

#### Endoscopic Mucosal Resection

Endoscopic mucosal resection (EMR) is an advanced endoscopic technique used for removal of premalignant or malignant lesions that are mainly confined to the mucosa, or in some cases superficial submucosa.<sup>19</sup> One principle method of EMR is the use of a liquid cushion to expand the submucosa and minimize transmural cautery damage. Using this technique, the specimen usually includes mucosal and submucosal tissue. In general, EMR requires some measure of confidence that a lesion is, in fact, confined to the mucosa or submucosa. Many endoscopists rely

**FIG 5.1** **A**, Standard and **B**, jumbo-sized pinch biopsy forceps.

**FIG 5.2** **A**, Microscopic photograph of an endoscopic mucosal resection specimen with high-grade dysplasia in Barrett's esophagus. Arrows point to the lateral mucosal resection margins consisting of squamous (right) and columnar (left) tissue. The star designates a high-grade dysplasia focus, shown at high magnification in **B**. **C**, Lateral resection margin showing cauterized Barrett's esophagus but without dysplasia.

on endoscopic ultrasonography (EUS) to determine the depth of a particular lesion before choosing to perform an EMR procedure. The accuracy of high-frequency EUS (15 or 20 MHz) may be as great as 95% for determining whether a lesion is limited to the mucosa.

Several variations of the EMR technique are currently used.<sup>21</sup> Many rely on submucosal injection of liquid, most often saline. Less commonly, diluted epinephrine is used in addition to saline, which helps constrict small blood vessels at the base of the lesion. Other techniques advocate hypertonic solutions of 3.5% saline or 50% dextrose or sodium hyaluronate. The quantity of liquid injected also varies; the idea is that the injected lesion should appear to be raised by a cushion of liquid above the mucosal surface before resection is attempted. Failure to "lift" the lesion despite generous use of submucosal saline (the so-called nonlifting sign) may be an indication that a lesion has spread deeper into the bowel wall.<sup>21</sup>

Two major types of EMR techniques are used: the lift and cut technique (also known as strip biopsy), without the use of suction, and aspiration mucosectomy, which employs suction as part of the method. Both methods typically also feature a snare that is used around the lifted lesion. Aspiration mucosectomy, in particular, has been widely successful for removing lesions in the GI tract.<sup>22</sup> A newer EMR technique is similar to aspiration mucosectomy, but after the lesion has been suctioned into the cap, a small rubber ring is released around the base of the lesion, similar to the method used during endoscopic variceal ligation. Once suction is released, the lesion appears contained within a "pseudopolyp" that may be removed by snare cautery. This is known as band-ligation EMR.<sup>23,24</sup>

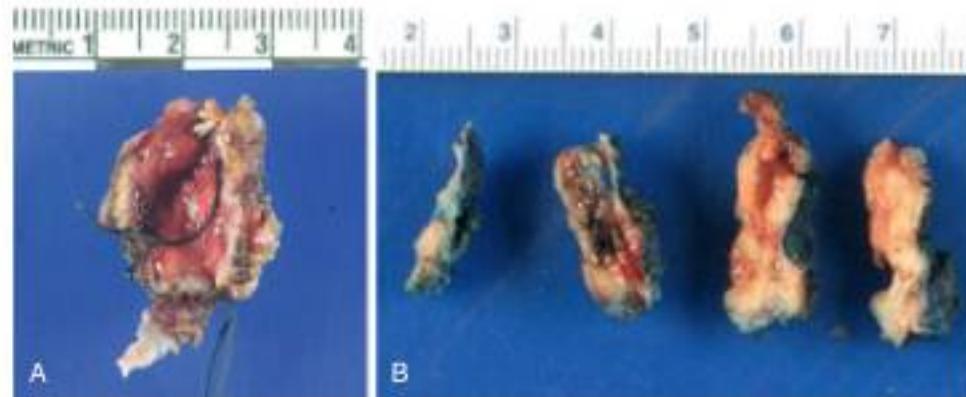

Endoscopists and the pathologists who handle EMR specimens must recognize that these samples may contain cancer; therefore they should be handled appropriately and oriented correctly for optimal pathologic tumor staging, including assessment of depth of invasion, and the margins of resection, including assessment of the deep submucosal margin (Fig. 5.3). EMR allows the endoscopist to attempt an en bloc resection and thus, potentially, to completely resect an early malignant lesion. En bloc resection is limited, however, to lesions no more than 1.5 to 2 cm in largest diameter.<sup>25</sup> If deep margins are positive for neoplasia, surgical resection of the affected region is advocated.<sup>26</sup> Current indications for EMR include superficial carcinoma of the esophagus or stomach in patients who are not candidates for surgery; unifocal high-grade (or low-grade) dysplasia in BE; and large, flat colorectal

adenomas (which might otherwise require piecemeal resection) regardless of the degree of dysplasia. EMR as a form of primary therapy for small, superficial cancer has gained increasing popularity in the United States but is even more widely used in Japan, where early gastric cancer is more common. EMR is also used as a form of primary therapy for small submucosal lesions, such as rectal carcinoid tumors or leiomyomas. In many cases, the submucosal lesion can be completely resected.<sup>27</sup>

### Brush Cytology Samples

Brush cytology is a method used for broad sampling of the mucosal surface.<sup>28,29</sup> Cytology brushes share common design features: bristles, usually composed of nylon or metal fibers, branch off a thin metal shaft that runs lengthwise within a protective plastic sheath. The various brushes that are currently available do not seem to vary in terms of performance characteristics. The cytology brush is passed through an accessory channel of an endoscope. The end of the sheath is passed out of the tip of the endoscope, and the bristle portion of the brush is then extended from the sheath. The brush is rubbed back and forth several times along the surface of the mucosa, lesion, or stricture, and is then pulled back into the sheath. The sheath is withdrawn from the endoscope, and the brush is pushed out of the sheath, thus exposing the bristles. The bristle portion of the brush may be cut off, placed into fixative, and sent in its entirety to the cytopathology laboratory. Alternatively, the bristles may be rolled against a glass slide in the endoscopy suite. The slides should be immediately sprayed with fixative or submerged within it and subsequently delivered to the cytopathologist. If smears are made in the endoscopy suite, little additional benefit is derived from inclusion of the bristles for cytopathologic analysis.<sup>30</sup>

Brush cytology is often used in the pancreaticobiliary tree in order to sample strictures in the pancreaticobiliary tract, or in the esophagus to sample esophageal plaques or lesions suspicious of infectious esophagitis.<sup>31,32</sup> Of the three major potential infections of the esophagus, *Candida albicans* and herpesvirus are characterized by having organisms in surface exudate and surface epithelial slough.<sup>33</sup> In contrast, cytomegalovirus is typically present deeper in the tissue stroma and is not commonly detected in cytologic smears of exudate. Smears of exudates for cytologic examination for herpesvirus or *Candida* may provide a rapid diagnosis.<sup>34</sup> Brushings may also be used for viral culture or polymerase chain reaction (PCR) for herpesvirus, if clinically indicated.<sup>32</sup> For viral culture, the use of a culture medium is

**FIG 5.3** Gross photograph of endoscopic mucosal resection specimen **A**, before and **B**, after sectioning.

needed; a second brushing may be swirled around in a culture medium, or the brush tip may be cut off with wire cutters and left in the bottom of the culture medium container.

Cytologic brushings of biliary strictures are an important tool in the assessment of strictures within the pancreaticobiliary tree. Endoscopic biopsy in this location is problematic, largely due to the inability to access and visualize lesions adequately to be sampled.<sup>35</sup> Cancer detection rates with brush cytology sampling rates are disappointing.<sup>36</sup> Combining brush cytology with ancillary techniques, such as fluorescence *in situ* hybridization, improves accuracy and diagnostic yield.<sup>37</sup>

Brush cytology has been proposed as an alternative method of surveillance in patients with BE and offers the advantages of an inexpensive method and potential for sampling over a greater area of the esophagus.<sup>38,39</sup> In a prospective study by Kumaravel et al (2010), 530 patients were assessed using paired cytologic brushings and histologic biopsies. A concordance rate of 80% between the two methods was documented.<sup>39</sup> Cytology excelled at detection of high-grade dysplasia (HGD) and adenocarcinoma, but it had poor sensitivity for detection of low-grade dysplasia (LGD). Brush cytology has also previously been used in combination with fluorescence *in situ* hybridization for detection of DNA abnormalities in a large cohort of BE patients.<sup>40</sup> In another study by Timmer et al (2014), DNA gains detected in brush cytology samples of BE patients may predict a lower response rate to endoscopic therapy.<sup>41</sup>

### Tissue Fixation

Once a biopsy has been obtained and the forceps removed from the endoscope, the tissue is retrieved or dislodged from the forceps and immediately submerged completely into a container with appropriate fixative. Avoidance of prolonged time before the tissue is placed in fixative is imperative. Care also should be taken to avoid crushing or excessively shaking the tissue sample, because this can introduce artifacts in the tissue that limit histologic assessment. For example, excessive shaking before complete fixation can lead to shearing and detaching of the surface epithelium from the mucosa and result in "denuded" mucosal sections. Excessive shaking may also shear delicate inflamed tissues, leading to tissue fragmentation that also precludes optimal histologic assessment.

Timely fixation minimizes tissue autolysis and desiccation and helps preserve mucosal architecture. The most common fixative used for GI mucosal biopsies is 10% buffered formalin. Formalin provides excellent fixation, with tissue penetration occurring at approximately 1 mm per hour.<sup>42</sup> The volume of formalin used for fixation should be at least 10 times greater than the amount of tissue being fixed. Importantly, formalin fixed tissue is the optimal fixative for most histochemical and immunohistochemical stains routinely performed in most laboratories. In addition, formalin fixed tissue is also suitable for use in molecular DNA or RNA based tests, including PCR and fluorescent *in situ* hybridization (FISH).<sup>43-45</sup>

On occasion, the formaldehyde in formalin may be irritating to the eyes and upper respiratory tract of personnel. In addition, formaldehyde is classified by the Environmental Protection Agency as a probable human carcinogen, at a threshold of 1.0 ppm, which is well above the level that causes sensory irritation.<sup>46</sup> In pathology laboratories, ventilated hoods are used to limit exposure to formalin. In the endoscopy suites, typical occupational exposure to formalin is very brief, and special ventilation is not usually required in that hospital area.

In certain circumstances, it may be required to obtain endoscopic tissue for ancillary studies other than routine histologic examination. Samples obtained for specific tests, for example, flow cytometry, tissue culture, and electron microscopy, should be handled according to the guidelines in place at the home institution. One of the more common indications for ancillary studies is flow cytometry, which can be useful when a hematologic malignancy is suspected, such as lymphoma.<sup>47</sup> In this example, after tissue is obtained from the lesion of interest, the tissue should be kept unfixed to send for flow cytometry; fixative should be avoided before the fresh tissue is triaged for this test. Flow cytometry cannot be performed once the tissue is fixed, and it is therefore incumbent on the endoscopist to consider the possibility of a lymphoproliferative disorder and preserve fresh tissue. Similarly, microbial culture also requires fresh tissue samples. Specimens for culture should preferably be obtained first, to minimize any extraneous contamination concerns. Ideally, fresh and unfixed tissues should be delivered to the appropriate laboratory within a few hours, but storage at 4°C overnight is acceptable.

Other diagnostic considerations may require fixing tissue in glutaraldehyde if electron microscopy is needed, or in cell culture medium for cytogenetic karyotyping. In most cases, it is customary that tissue from the same lesion, or area, should also be submitted, in a separate jar with fixative, for routine histology. This extra step confirms and ensures that tissue from the area of interest submitted for ancillary studies was, in fact, representative of the lesional tissue. Appropriate tissue triage is best achieved through collaborative discussion between the endoscopist and pathologist to understand these special procedures which frequently vary between institutions. Pathologists can also alert histotechnologists or pathology assistants in the laboratory to any special instructions to ensure timely and appropriate handling of the specimen.

### Laboratory Tissue Processing

Once the specimen arrives in the pathology laboratory, the tissue is processed and glass slides are generated. Tissue processing is performed by histotechnologists, laboratory technicians who specialize in tissue handling. Histotechnologists retrieve tissues from the specimen jars and transfer the biopsy sample to a standard tissue cassette measuring 3 × 2.5 × 0.4 cm. During this step, the tissue fragments in each jar are measured, counted, and recorded as part of the gross description of the pathology report. Typically, all the tissue from one jar is placed into one cassette. However, when the number of tissue fragments is high, which may in subsequent steps limit ideal tissue orientation during paraffin embedding, the tissue fragments from one jar may be divided among two or more cassettes. The cassettes are placed in an automated tissue processor, where the tissue is dehydrated and cleared in preparation for paraffin wax embedding, a process lasting several hours or overnight.

After tissue processing, histotechnologists retrieve the tissue cassettes from the processor and embed the tissue in paraffin wax to create formalin fixed paraffin embedded (FFPE) tissue blocks. During embedding, histotechnologists orient mucosal samples "on edge" to present the normal mucosal architecture at microscopy. Tiny and fragmented specimens often cannot be well oriented. Proper orientation aids in assessment of the amount of lamina propria inflammation, focal lesions such as granulomas, and intraepithelial lymphocytes (IELs) (especially small bowel). In the colon, for example, oriented sections permit accurate assessment of crypt architecture.

Orientation of intact polypectomy specimens is particularly important and requires diligent effort prior to tissue processing. The gross pathologic size and surface configuration (e.g., bosselated, villiform, or sessile) of the polyp should be noted, and the base of the polyp should be identified. Regardless of the configuration or presence of a stalk, the base of the polyp should always be inked to aid in the subsequent microscopic identification and examination of the polyp resection margins. Ink and cautery artifact on a microscopic slide are valuable landmarks for locating relevant resection margins. Small polyps (< 1 cm in diameter) should be bisected along the vertical plane of the stalk so that the surgical margin is included. Both halves of the specimen can then be submitted in one cassette for processing. For larger polyps (> 1 cm) that cannot fit easily in one cassette, the polyp is sectioned by trimming the sides away from the stalk. The stalk is submitted in a designated cassette, whereas the remainder of the polyp is submitted in separate cassettes.

To create microscopic slides, histotechnologists cut FFPE tissue blocks using a microtome, typically in a thickness of 4 microns, and place the cut tissue sections on glass slides, which are then stained with hematoxylin and eosin for routine microscopy. FFPE tissue blocks can be stored indefinitely for future use, if the clinical need arises. Tissue blocks can be recut numerous times, such as to create additional slides for various uses, including histochemical stains to detect infectious organisms or to better characterize tumors. In addition, DNA and RNA can be extracted from FFPE blocks for molecular analysis and other nucleic acid based tests.<sup>44–48</sup>

## DISEASE SPECIFIC APPROPRIATE TISSUE SAMPLING

### Esophagus

#### Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD), which occurs at an estimated prevalence rate of 20% to 40%, is a very common indication for endoscopic examination. Establishing a diagnosis

of GERD includes the assessment of clinical features and endoscopic findings. Upper endoscopy (EDG) is not required in the presence of typical GERD symptoms. Endoscopy is recommended in the presence of "alarm" symptoms and for screening of patients at high risk for complications.<sup>49,50</sup>

Endoscopically, GERD can present with a variety of changes, ranging from normal to erosive esophagitis. Strictures and BE are common complications of GERD.<sup>51,52</sup> In the absence of endoscopically visible BE, there are no universally accepted biopsy protocols for the evaluation of GERD. Histologic changes in endoscopically normal appearing distal esophagus may show nonspecific features of "minimal change" esophagitis, such as papillary elongation, basal cell hyperplasia, and intercellular edema. The clinical implications of these histologic features in the absence of endoscopically visible changes are unclear. Biopsies of normal mucosa in the setting of GERD, where other diagnoses are not suspected, are not currently recommended (Table 5.1).<sup>49,53</sup>

Biopsies of endoscopically visible changes in GERD patients often reveal "active" esophagitis, a nonspecific injury pattern that can result from a variety of causes. GERD-associated reflux esophagitis produces a characteristic, although nonspecific, tissue injury pattern. Features of untreated active esophagitis include basal cell hyperplasia, elongation of the lamina propria papillae, epithelial cell necrosis, increased intraepithelial inflammation (including eosinophils, neutrophils, and lymphocytes), distended pale squamous "balloon" cells, intercellular edema, and, in severe cases, surface erosions or ulceration. Histologically, reflux changes are typically distributed over the distal 8 to 10 cm of the esophagus in a patchy fashion, with the most demonstrative changes typically present in the distal esophagus, and less intense change located more proximally.<sup>54</sup> Multiple biopsies may be necessary to consistently demonstrate histologic abnormalities. Because biopsy specimens from the lower 1 to 2 cm of the esophagus, even in asymptomatic subjects, often reveal evidence of mild basal cell hyperplasia, diagnostic biopsy specimens should also be obtained more than 2 cm above the level of the gastroesophageal junction (GEJ) to diagnose esophagitis reliably.<sup>54–56</sup>

**TABLE 5.1 Recommendations for Optimum Location and Number of Mucosal Biopsies for**

Disease	Location and Number of Biopsy Samples
GERD <sup>49,50,53</sup>	Screening endoscopy and biopsy in high risk patients and those with alarm symptoms
Eosinophilic esophagitis <sup>57</sup>	Multiple esophageal biopsies from several areas, and one biopsy each from duodenal and gastric mucosae Two to four biopsies from the proximal (1) and distal (1) esophagus (yield: 80%) Up to five tissue samples, including biopsies from the proximal, mid, and distal esophagus (yield: 100%)
Barrett's esophagus <sup>58,59</sup>	Detection of goblet cells: Four targeted biopsies that straddle the neosquamocolumnar junction, or Eight random samples obtained from the columnar-lined esophagus Surveillance for dysplasia: Four-quadrant biopsies per 2 cm of columnar-lined esophagus Additional sampling of endoscopically visible lesions Surveillance for early carcinoma in patients with high-grade dysplasia Four-quadrant biopsies per 1 cm of columnar-lined esophagus Additional sampling of endoscopically visible abnormalities
Chronic gastritis <sup>60,61,62,63,64,65</sup>	Five biopsies from antrum (2), corpus (2), and incisura angularis (1) Surveillance for dysplasia: Minimum of five biopsies from antrum (2), corpus (2), and incisura angularis (1) Additional sampling of endoscopically visible abnormalities If dysplasia is present: Follow up every 3 months for 1 year with topographic mapping of the stomach
Celiac disease <sup>66</sup>	Three biopsies of the duodenal bulb (1), proximal duodenum (1), and distal duodenum (1)

GERD, gastroesophageal reflux disease.

Pinch biopsies obtained through standard endoscopes are often not adequate for evaluation of early histologic changes resulting from reflux because they usually do not include the entire thickness of the mucosa and are difficult to orient. Endoscopes with a large-caliber biopsy channel and jumbo biopsy forceps should be used to facilitate accurate histologic diagnosis. Use of jumbo forceps does not increase the rate of complications related to endoscopy; rather, it greatly improves the quality of the histologic specimens.<sup>1</sup>

### Barrett's Esophagus

BE is characterized by the conversion of normal squamous epithelium of the esophagus into metaplastic columnar epithelium, caused by chronic GERD in the vast majority of cases.<sup>57,58</sup> Patients with BE have an increased risk of developing dysplasia and adenocarcinoma. For these reasons, it is highly recommended that patients with BE undergo periodic endoscopic surveillance to detect preinvasive neoplasia (dysplasia) and prevent the development of cancer.<sup>59,60</sup>

The American College of Gastroenterology (ACG) and American Gastroesophageal Association (AGA) define BE as endoscopically recognizable columnar metaplasia of the esophageal mucosa that is confirmed pathologically to contain intestinal metaplasia (IM), the latter defined by the presence of goblet cells.<sup>59,61</sup> Based on this definition, both the endoscopic and pathologic components are required to establish a diagnosis of BE. According to this strict definition, patients who have IM (goblet cells) of the gastric cardia are not included in this disease. Columnar mucosa is visible endoscopically and is most often grossly described as *salmon-pink* gastric-type mucosa in the distal esophagus.<sup>57,58</sup> As much as one-third of GERD patients who lack endoscopically visible columnar mucosa within the distal esophagus show IM (goblet cells) in their otherwise anatomically normal GEJ, and these patients do not qualify as having BE based on the previously mentioned ACG and AGA guidelines.<sup>51,62</sup> This position is based on the assumption that the presence of a few intestinalized glands in the GEJ region of patients without endoscopically apparent columnar metaplasia of the distal esophagus does not confer the same increased risk of malignancy as endoscopically visible BE.<sup>63</sup> There is an absence of worldwide agreement that IM (goblet cells) should be required for a diagnosis of BE. For instance, in both the United Kingdom and Japan, IM is not required to establish a diagnosis of BE.<sup>64-66</sup> Studies suggest that most patients with at least 2 cm of columnar-lined esophagus are found to have IM if enough biopsy samples are obtained from the columnar-lined segment.<sup>67</sup> Therefore sampling error is a confounding factor. Several studies have found a similar risk of progression to dysplasia or cancer in patients with and without goblets cells in columnar-lined esophagus.<sup>68,69</sup>

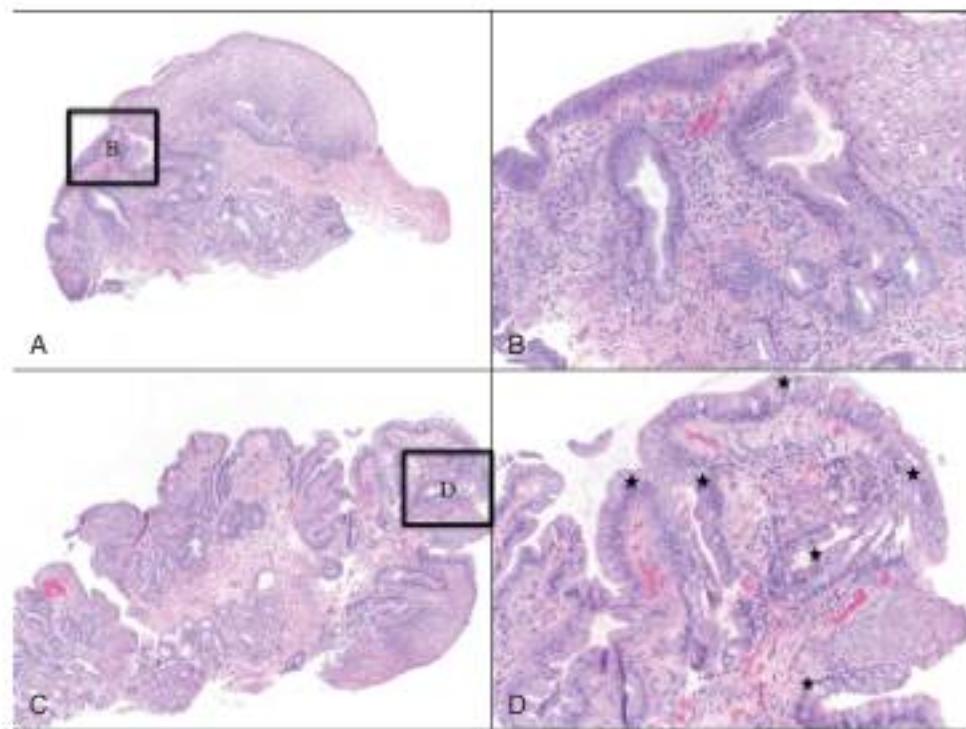

Several anatomic landmarks are important for endoscopists to identify when evaluating patients with possible BE. The GEJ, which is the junction between the tubular esophagus and the proximal stomach, is defined in North America as the most proximal aspect of the gastric folds.<sup>70</sup> The squamocolumnar junction (SCJ), also known as the Z-line, is the junction of squamous and columnar mucosa. It does not necessarily correspond to the location of the GEJ, and is irregular in many apparently normal individuals with and without GERD symptoms. The endoscopist should provide the pathologist with knowledge about the relationship of the SCJ to the GEJ (i.e., whether it is located at or above the GEJ) and the location of the biopsy relative to these anatomic landmarks. Therefore if the SCJ is observed

to be proximally displaced relative to the GEJ, biopsies of the GEJ, the SCJ, and the intervening (salmon-pink colored) columnar mucosa should be obtained to help establish a diagnosis of BE (see Table 5.1).

An endoscopic impression of BE may be difficult if there are very short (ultrashort) segments of columnar mucosa in the esophagus.<sup>62,71</sup> In addition, endoscopy is challenging in patients with hiatal hernia, which makes identification of the location of the proximal gastric folds difficult. In both normal individuals and in reflux patients without BE, very short segments of endoscopically visible mucosa within the distal esophagus/GEJ region are often composed of gastric cardiac or fundic-type mucosa, but without goblet cells. In these cases, the SCJ junction is usually irregular and may project for only a few millimeters into the distal portion of the tubular esophagus. Pathologists are often asked to evaluate "GEJ" or "irregular Z-line" biopsies to "rule out BE." In the majority of cases, it is not possible for pathologists to accurately determine the true anatomic origin of the biopsy (i.e., whether it was obtained from the distal esophagus or from the proximal stomach) when evaluating biopsies from the GEJ region. Goblet cells may be present in both the distal esophagus and gastric cardia and, when present, are histologically and histochemically identical.<sup>72,73</sup> However, some studies have identified a variety of morphologic features that, when present, help determine whether a biopsy with columnar mucosa from the GEJ originated in the distal esophagus. For instance, in a study by Srivastava et al (2007), mucosal biopsy samples from 20 patients with BE and from 20 patients with IM of the proximal stomach were evaluated. The authors found that the presence of several features, such as buried columnar epithelium, severe crypt atrophy and disarray, multilayered epithelium, and esophageal glands and/or ducts, were indicative of esophageal origin of the columnar mucosa in the biopsy sample and thus were significantly associated with BE.<sup>74</sup>

Traditionally, BE has been classified into long-segment (> 3 cm), short-segment (1–3 cm), and ultrashort-segment types (< 1 cm), depending on the length of involved esophageal mucosa.<sup>75,76</sup> However, the biologic significance of this classification system remains unclear. Several studies have evaluated the risk of dysplasia and cancer in relation to the length of BE. A 2013 multicenter cohort study suggests an 11% increased risk of HGD and carcinoma for every 1 cm increase in BE length.<sup>77</sup> The increased risk associated with longer lengths of BE has been attributed to a larger surface area at risk for neoplastic progression.

Microscopically, BE is characterized by columnar epithelium composed of mucinous columnar cells with scattered goblet cells, enterocytes, and intermediate features of gastric/intestinal cells. Occasional Paneth cells and endocrine cells may be seen. Because of ongoing and recurrent inflammation, ulceration, and repair, nondysplastic BE typically shows mild architectural and cytologic changes that differ from normal intestinal epithelium. Nondysplastic BE has a relatively low nuclear-cytoplasmic (N:C) ratio and shows surface maturation. Goblet cells are irregularly distributed in BE and thus, multiple samples are usually required to detect them (Fig. 5.4). In one retrospective study of 1646 esophageal mucosal biopsies from 125 consecutive patients with BE, goblet cells were detected in 68% of cases when eight mucosal samples were taken and only in 35% when four samples were taken; no significant benefit was found in goblet cell detection with more than eight biopsies (see Table 5.1).<sup>67</sup> Another study found that goblet cells were more commonly detected at the

**FIG 5.4** Distal esophageal biopsies from a patient with Barrett's esophagus showing fragments of squamocolumnar junctional mucosa without (**A** and **B**, low and representative high magnification, respectively) and with (**C** and **D**, low and representative high magnification, respectively) intestinal metaplasia. Stars highlight the scattered goblet cells.

neosquamocolumnar junction than in the distal esophagus (94% vs. 39%, respectively).<sup>78</sup>

Dysplasia is defined as neoplastic epithelium confined to basement membrane. Endoscopically, dysplasia may be undetectable or may appear flat, plaque-like, nodular, polypoid, or ulcerated. The histologic diagnosis and grading of dysplasia is based on evaluation of both cytologic and architectural abnormalities.<sup>79</sup> Intestinal type dysplasia is graded as LGD or HGD. LGD is composed of columnar cells with nuclear elongation, hyperchromasia, stratification, and retained polarity, and is often described as resembling conventional colonic tubular adenoma. In contrast, HGD exhibits architectural abnormalities and greater degree of cytologic atypia, such as marked nuclear pleomorphisms with round vesicular nuclei, prominent nucleoli, and loss of polarity. Unfortunately, there is a well-established, high degree of interobserver variability in interpretation of cytologic and architectural features among both expert GI pathologists and general pathologists.<sup>80–82</sup> Many pathologists, particularly those from Europe and Asia, prefer the more recently proposed Vienna classification system.<sup>83</sup> The Vienna system uses the terms "noninvasive neoplasia" instead of dysplasia and "suspicious for invasive carcinoma" for lesions that show equivocal cytologic or architectural features of tissue invasion. The categories in the Vienna system are as follows: negative for neoplasia, indefinite for neoplasia, noninvasive low-grade neoplasia, noninvasive high-grade neoplasia (including noninvasive carcinoma in situ and suspicion of invasive carcinoma), and invasive neoplasia (intramucosal and submucosal). The Vienna system was developed in an effort to reduce discrepancies in interpretation of dysplasia between Western and Japanese pathologists and to help reach a

worldwide consensus on the nomenclature of GI neoplasia. Recent reports have also described nonintestinal forms of dysplasia, namely foveolar and serrated dysplasia, which at this time are not well characterized and the natural history of these types of dysplastic changes is poorly understood.<sup>84–86</sup>

Various biomarkers of progression have been studied as potential adjuncts for the diagnosis of dysplasia. For example, genomic instability as measured by copy number alteration and loss of heterozygosity were shown to be useful markers of progression.<sup>87</sup> Another retrospective, double-blinded validation study of eight BE methylation biomarkers proposed a methylation biomarker-based panel to predict neoplastic progression in BE with potential clinical value in improving both the efficiency of surveillance endoscopy and early detection of dysplasia.<sup>88</sup> More recently, p53 overexpression was associated with an increased risk of neoplastic progression in patients with BE.<sup>89</sup> Despite these advances, at present, there are no biomarkers, or panel of biomarkers, that have been validated in large prospective cohort studies. Morphologic assessment of dysplasia remains the gold standard for evaluating dysplasia. In their most recent position statement, the AGA does not recommend the use of molecular biomarkers to confirm a histologic diagnosis of dysplasia for patients with BE at this time.<sup>81</sup>

In some instances, a definite diagnosis of dysplasia cannot be established, and the term *indefinite for dysplasia* is used. This can occur when biopsies contain active inflammation, ulceration, or postulcer healing, and it may be difficult for pathologists to determine whether a biopsy with atypical changes represents true dysplasia or extreme regenerative changes. Other factors that can lead to uncertainty include technical or processing

artifacts (for example, poor orientation, lack of surface epithelium, crush artifact). The rate of a diagnosis of indefinite for dysplasia varies widely between pathologists and is in part based on individual experience.<sup>50</sup> It is important to recognize that indefinite for dysplasia is a provisional diagnosis.

Tissue sampling in the setting of BE has been described in great detail in several other publications and various society guidelines.<sup>50,51</sup> Currently, recommended endoscopic surveillance consists of four-quadrant biopsies at 2-cm intervals with the use of jumbo biopsy forceps. Data that support this systematic sampling protocol include a study by Abela et al (2008), which found that systematic surveillance detected HGD, which was almost always amenable to endoscopic resection, in 2.8% of patients, compared to 0% in patients with nonsystematic sampling.<sup>51</sup> Furthermore, none of the patients undergoing systematic surveillance developed adenocarcinoma, whereas three patients with nonsystemic sampling died of invasive adenocarcinoma. In addition, specific endoscopic mucosal abnormalities such as ulcers, irregular lesions, nodules, and polyps should also be sampled, and these lesions should be submitted separately.

The recommended surveillance interval for dysplasia in patients with BE is determined by the presence and degree of dysplasia found. In the absence of dysplasia, the surveillance interval is every 3 to 5 years, with four-quadrant biopsies every 2 cm (see Table 5.1). If the pathology is indefinite, the biopsy should be reviewed by an expert GI pathologist. Medications for reflux treatment should be maximized to reduce the presence of inflammation, and then EGD with biopsies should be repeated. The presence of LGD should be confirmed by endoscopy within 6 months, followed by surveillance every 12 months. Studies have shown that endoscopy with magnification and narrow band imaging (NBI) allows for better localization of HGD and may also allow more targeted and fewer biopsies. For LGD, ablation therapy has also shown an advantage over surveillance alone. For instance, a 2014 multicenter randomized trial of 136 patients with LGD showed that ablation therapy reduced the risk of progression to HGD and adenocarcinoma from 26.5% to 1.5% compared with surveillance alone, over a 3-year follow-up.<sup>52</sup> In patients with known or suspected dysplasia, biopsies should be obtained at 1-cm intervals instead of the standard 2 cm intervals (see Table 5.1). A study of 45 BE patients with HGD reported that biopsies obtained at 2-cm intervals missed 50% of early cancers that were detected when sampling at 1-cm intervals was performed.<sup>53</sup>

Patients with flat HGD confirmed by an expert GI pathologist should undergo a repeat endoscopy within 3 months with four-quadrant biopsies every 1 cm if an eradication method is not used. The prevalence of cancer in resection specimens from patients who have undergone an esophagectomy for HGD ranges from 5% to 41%, and the rate of progression to cancer in patients with HGD approaches 30% at 10 years. Options for patients with flat HGD include intensive surveillance (every 3 months), esophagectomy, and ablative therapies such as BARRX radiofrequency ablation (Medtronic, Minneapolis, MN). It is recommended that patients with HGD in an area of mucosal irregularity should undergo endoscopic mucosal or surgical resection (see Fig. 5.2). EMR functions as both a diagnostic and a therapeutic procedure, and there is a growing trend toward recommending esophagectomy only for patients with either extensive HGD or invasive carcinoma.<sup>54,55</sup> Because EMR specimens typically consist of larger pieces of tissue than biopsies, which can also be optimally oriented during processing, EMR increases diagnostic accuracy

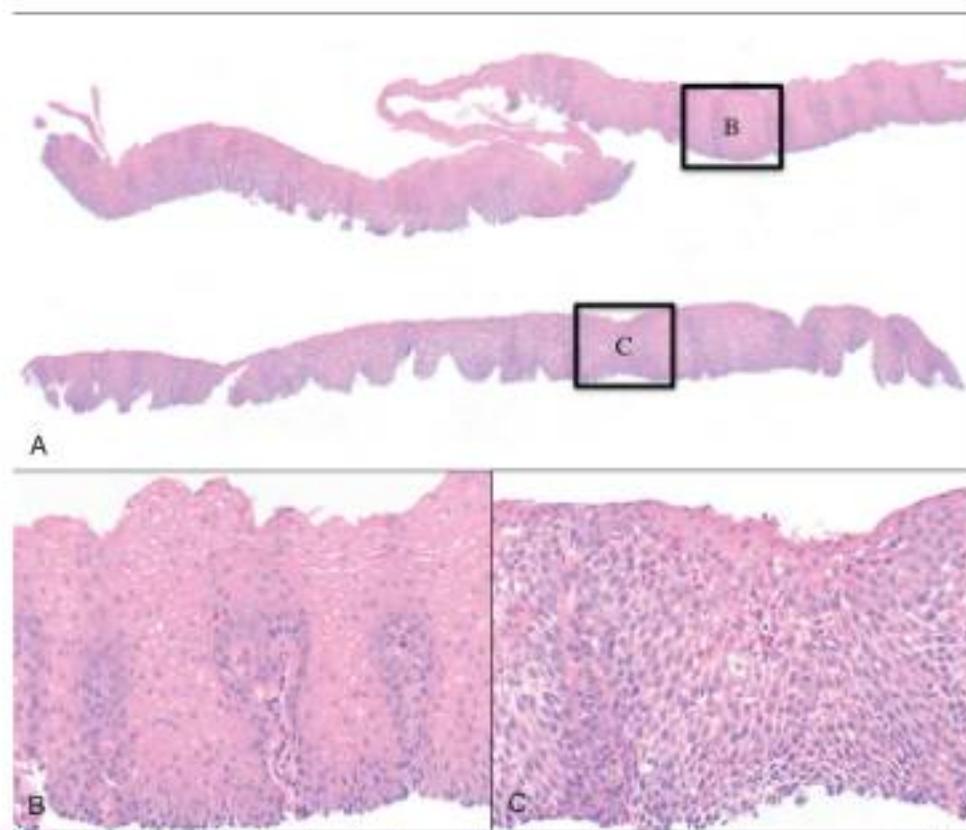

and allows pathologists to provide more accurate pathologic diagnostic information. For example, in a study by Mino-Kenudson et al (2007), 37% of cases of BE with dysplasia diagnosed in biopsies had a change of grade when evaluated on EMR specimens.<sup>56</sup> Biopsies underreported the grade of neoplasia in 21% of cases and overreported the grade in 16%. In a recent multicenter cohort study of 138 BE patients (including 15 LGD, 87 HGD, and 36 early adenocarcinoma) undergoing biopsies followed by EMR within 6 months, EMR evaluation resulted in a change in histologic diagnosis in approximately 30% of patients, irrespective of the presence or absence of visible lesions.<sup>57</sup>

### Eosinophilic Esophagitis

The diagnosis of eosinophilic esophagitis (EoE) is based on clinicopathologic correlation, with clinical, endoscopic and histologic findings each serving an important role in assessing a patient with dysphagia. EoE is a chronic, immune mediated disease characterized by esophageal eosinophilia and esophageal dysfunction, affecting children and adults. Endoscopically, patients with EoE can show several characteristic features, including esophageal rings, mucosal plaques or exudates, longitudinal furrows, edema, diffuse esophageal narrowing, narrow-caliber esophagus, and mucosal tears. In some cases, the esophagus appears entirely normal, but more than 90% of affected patients display one or more of these endoscopic abnormalities.<sup>58</sup> However, these endoscopic features have been described in other conditions and are not pathognomonic of EoE.

Histologically, many of the features of EoE overlap significantly with those of GERD, particularly in distal esophageal biopsies. EoE biopsies usually show numerous intraepithelial eosinophils, typically 15 or more per high-power field.<sup>59</sup> Severe GERD produces pronounced eosinophilia in this range in only a minority of cases, and in these cases, it is unclear if the patients have GERD and EoE concurrently. However, because intraepithelial eosinophils in both conditions may be patchy in distribution, sampling error can affect the ability to establish a correct diagnosis (Fig. 5.5).<sup>60</sup> Although not pathognomonic, additional histologic features of EoE that can aid in establishing the diagnosis include eosinophilic microabscesses, surface layering of eosinophils, surface sloughing of squamous cells mixed with abundant eosinophils, and extracellular eosinophilic granules. The distribution of disease is important, because EoE often involves long segments of the esophagus, may be patchy or focal, and typically involves the proximal or middle esophagus and the distal esophagus or GEJ equally.<sup>59,60</sup> In contrast, patients with GERD typically have higher eosinophil counts in the distal esophagus, an area where reflux affects the esophagus more severely, than in the proximal esophagus.

Esophageal biopsies are the only reliable diagnostic test for EoE, and therefore biopsy is required to establish the diagnosis.<sup>61</sup> According to experts panels and the ACG guidelines, in patients with suspected EoE, it is recommended that two to four biopsies be obtained from at least two different locations in the esophagus, most typically in the distal and proximal halves of the esophagus, regardless of endoscopic findings (see Table 5.1).<sup>62</sup> Biopsies targeting areas with abnormal endoscopic findings (such as rings, furrows, and plaques) are also reasonable. An interdisciplinary panel of 33 expert physicians recommends taking two to four biopsy samples from the proximal and distal esophagus, regardless of the endoscopic appearance (see Table 5.1). Biopsies should be fixed in 10% buffered formalin, which preserves eosinophils better than alternative fixatives, such as Bouin's preservative.<sup>63</sup>

**FIG 5.5** **A**, Eosinophilic esophagitis showing patchy involvement, low power view. Higher magnification shows **B**, rare scattered eosinophils in one portion of the specimen and **C**, more than 30 eosinophils per high power field in a different focus.

In addition, gastric antrum and duodenum biopsies should also be obtained if there is a clinical suspicion of more widespread eosinophilic gastroenteritis.

#### Infectious Esophagitis

Infectious esophagitis is an important cause of esophagitis, particularly in immunocompromised patients, but also in immunocompetent patients.<sup>103,104</sup> The most common causes of infectious esophagitis are viruses and fungus (Fig. 5.6). Cytomegalovirus (CMV) infects mesenchymal and columnar cells and presents macroscopically as ulcerative lesions. Biopsy for CMV detection should be concentrated at the ulcer base to optimize sampling and diagnostic accuracy.<sup>105</sup> In a study of HIV-infected patients with esophageal ulcers, three forceps biopsy samples from the ulcer base were diagnostic in 80% of patients with CMV esophagitis, with a maximum of 10 biopsy samples needed to confirm the diagnosis in the remaining patients.<sup>106</sup> The biopsy samples were examined using standard histopathologic methods, with *in situ* hybridization or immunohistochemical stains as needed. Qualitative CMV PCR of biopsy samples is more sensitive than standard histopathology, but likely detects latent, as well as clinical, disease. Data are inconsistent regarding the benefit of viral culture in the evaluation of CMV esophagitis. Herpes simplex virus infects squamous epithelial cells, usually present at the lateral margin of ulcers and erosions; therefore mucosal biopsy samples of the ulcer margin have the highest diagnostic yield (see Fig. 5.6C, D). Viral culture and PCR can aid in diagnosing herpes simplex virus esophagitis.<sup>107</sup> There are

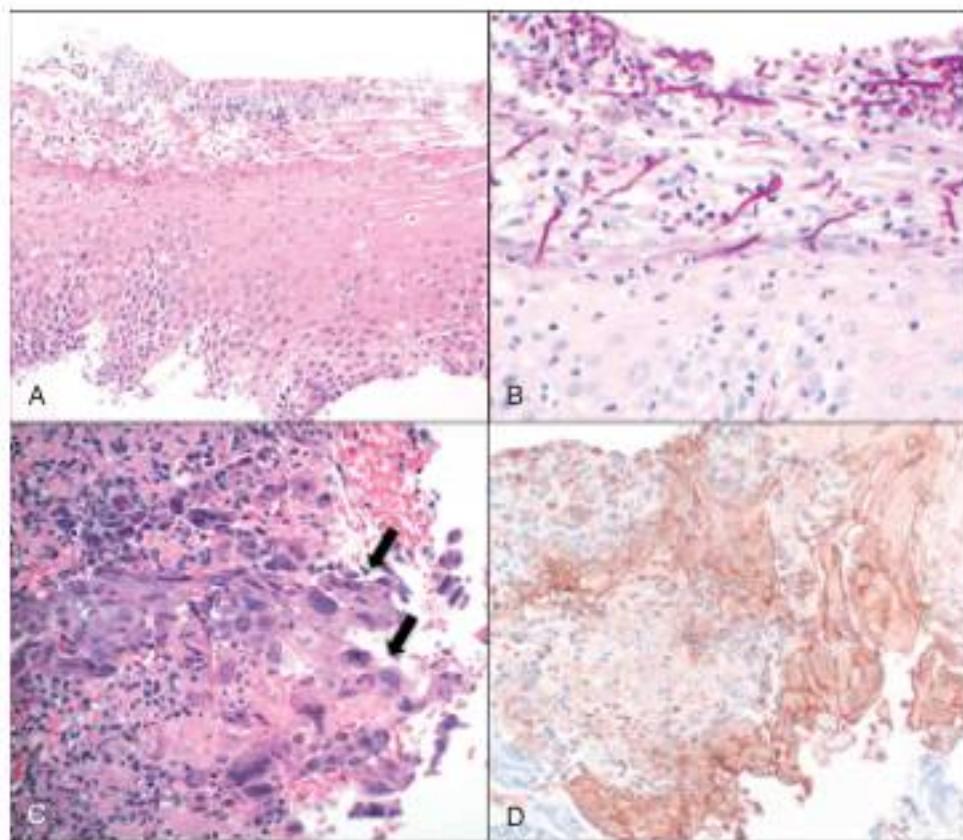

limited data on the optimal diagnostic technique for esophageal candidiasis (see Fig. 5.6A, B). White plaques are a characteristic finding and are recommended as the site of sampling, either as pinch biopsy or brush cytologic assessment.<sup>107</sup> Cytologic brushing may be more sensitive than histology for diagnosis.<sup>108,109</sup>

#### Stomach

##### *Helicobacter pylori*

*Helicobacter pylori* (HP) gastritis affects two-thirds of the world's population and is one of the most common chronic inflammatory disorders of humans.<sup>110</sup> Although chronic HP gastritis is asymptomatic in most infected individuals, its impact on human health is profound. HP gastritis confers a 15% to 20% lifetime risk for peptic ulcer disease, and 70% of gastric cancers and most primary gastric mucosal-associated lymphoid tissue (MALT) lymphomas are directly linked to chronic HP infection. In one British community, HP was estimated to be responsible for approximately 5% of all GI ailments.<sup>111</sup>

Because most patients with early HP gastritis do not undergo endoscopy, information regarding the clinical, endoscopic, and pathologic aspects of acute HP infection is limited to a few well-documented case reports, human ingestion studies, and analyses of infections acquired from inadequately disinfected endoscopic instruments.<sup>112</sup> Endoscopically, manifestations of acute or early HP gastritis are typically found in the antrum and characterized by hemorrhagic lesions and multiple erosions or ulcers. There are no distinct endoscopic patterns of chronic HP gastritis. Depending on the stage and type of gastritis, hyperemia,

**FIG 5.6** **A**, Candida esophagitis with superficial exudates composed of sloughed squamous epithelium and inflammatory cells. **B**, Candida organisms are highlighted by periodic acid Schiff with diastase stain. **C**, Herpes simplex virus esophagitis with superficial epithelial necrosis and sloughing, and herpetic inclusions within squamous cells (arrow). **D**, Immunohistochemical stain for herpes simplex virus confirms the diagnosis.

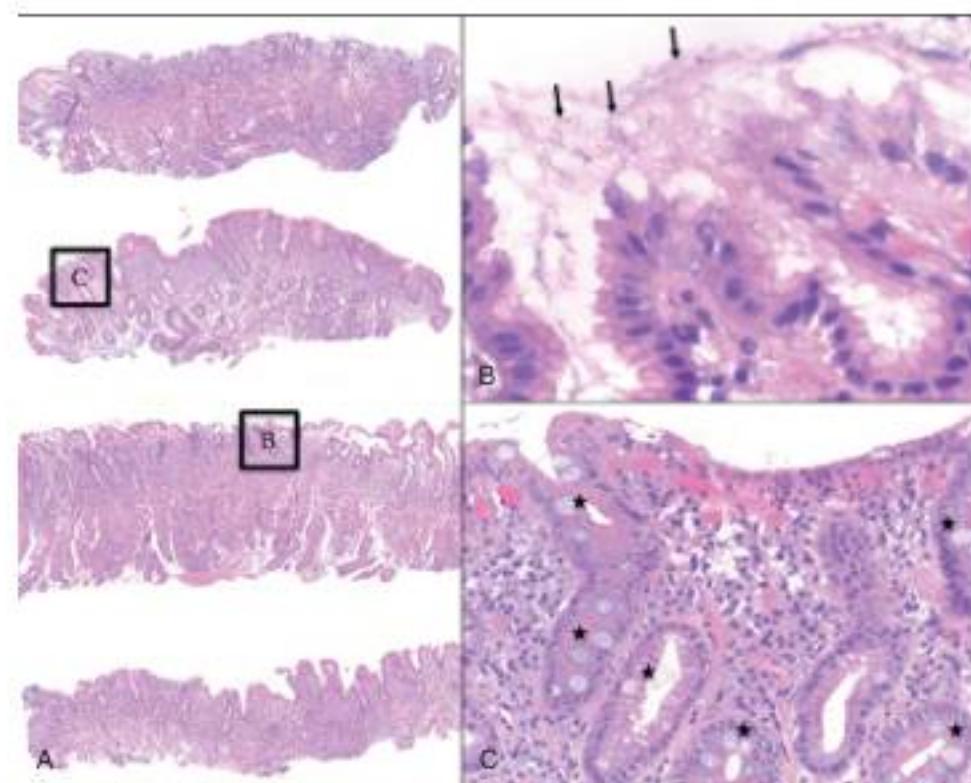

erosions, hypertrophy, and atrophy may coexist in various combinations. Unfortunately, none of these endoscopic features has proved useful for predicting the presence or absence of HP gastritis. Endoscopists should not attempt to diagnose HP gastritis based solely on the gross appearance of the gastric mucosa. The diagnosis of HP gastritis rests on pathologic evaluation of gastric mucosal biopsies or detection of urease in mucosal specimens by the *Campylobacter*-like organism (CLO) test or the urea breath test.<sup>112</sup>

Microscopically, HP chronic gastritis is characterized by a prominent lymphoplasmacytic infiltrate of the lamina propria of gastric mucosa (Fig. 5.7). In addition, mucosal neutrophils are scattered within the lamina propria or within the surface or glandular epithelium. Abundant HP organisms are usually present, characteristically attached to the surface of mucus foveolar cells.<sup>113</sup> After successful eradication therapy, neutrophils disappear rapidly, and their continued presence is considered a valuable indicator of therapeutic failure.<sup>114</sup> The intensity of the mononuclear cell infiltrate typically declines quite slowly after successful eradication of infection. As many as 30% of patients have chronic inactive gastritis that persists for several years after eradication of the organism. Other features include the presence of lymphoid follicles with germinal centers, seen in nearly all HP infected patients.<sup>115</sup> Occasionally, lymphoid infiltrates may be large and irregular, with destructive lymphoepithelial lesions at the periphery. In this circumstance, the possibility of gastric

lymphoma should be considered; immunohistochemical and molecular tests are often used for this purpose.

Diagnosis of HP gastritis can be made using a variety of endoscopic methods, including tissue urease activity, histologic examination, and microbial culture. The choice of test depends on the prevalence of the disease in the local population, clinical suspicion, cost considerations, and local expertise. HP normally infects antral and corpus mucosa, but in the cardia, organisms may be difficult to detect. HP organisms rarely colonize intestinal epithelium, and in patients with extensive areas of metaplastic atrophy, organisms are usually confined to the nonmetaplastic, nonatrophic areas of mucosa. The sensitivity of these endoscopic tests may be decreased by proton pump inhibitors (PPIs), bismuth compounds, antibiotics, and acute GI bleeding. Specifically, in patients who use PPIs, HP organisms tend to be rare or absent in the antrum, and they may be difficult to detect in the corpus, even in the setting of chronic active inflammation.<sup>116</sup> In situations of reduced sensitivity, a negative urease test result should be confirmed using a second test, and histologic exam is a convenient alternative. Similarly, patients treated with antibiotics before gastric biopsy may demonstrate a markedly reduced number of organisms and often have atypical (coccoid) forms.

There is limited data on the optimal biopsy protocol for detection of HP. Several recommendations have been published. The updated Sydney system protocol recommends five biopsies: two from the antrum, one from the angularis, two from fundus/

**FIG 5.7** **A**, Four biopsy samples from a patient with *Helicobacter pylori* gastritis. **B**, *Helicobacter pylori* bacteria are present in the luminal aspect of the foveolar epithelium (arrows). Focal intestinal metaplasia is present within a fragment of antral mucosa **C**. Stars highlight glands with intestinal metaplasia.

body (see Table 5.1).<sup>117</sup> The updated Sydney system provides pathologists with guidelines for generating systematic, uniform, and clinically relevant diagnostic reports. Another approach suggests taking three biopsies, one each from the angularis, greater curvature, and lesser curvature. El-Zimanti and Graham (1999) reported that the three biopsy protocol compared favorably with the Updated Sydney five biopsy protocol, with both methods identifying 100% of infections in a retrospective study of 46 patients.<sup>118</sup>

Use of ancillary stains for detection of HP, although common, is highly variable across medical centers. Commonly used and relatively inexpensive stains, such as Giemsa and Diff-Quik, are adequate for identification of most cases of HP organisms. Recently, the Rodger C. Haggitt Gastrointestinal Pathology Society recommended the use of ancillary stains when biopsies show chronic or chronic active gastritis without detectable HP on routine H&E sections, but recommended that "up front" stains on all gastric biopsies are not necessary.<sup>119</sup> Immunohistochemical stains for HP increase sensitivity and are particularly useful for detecting coccoid forms of the organism, rare organisms located deep within the glands, and intracytoplasmic organisms. After HP treatment, organisms may be best visualized with an immunohistochemical stain if chronic gastritis persists.

HP gastritis is associated with several possible complications. Chronic HP infection is a strong risk factor for development of gastric cancer, particularly the intestinal type, as well as lymphoma, particularly low-grade extranodal marginal zone lymphoma of mucosal-associated lymphoid tissue (MALT lymphoma). In

certain regions of the world, metaplastic atrophic gastritis develops in a considerable proportion of infected persons, and this condition is a precursor to gastric carcinoma. HP gastritis with metaplasia is histologically characterized by the presence of IM and gastric gland atrophy, usually oxytic, present in a patchy manner through the body and fundus (see Fig. 5.7C). In one study comparing HP infected patients with controls, Xia et al (2000), found that a greater proportion of HP infected individuals showed antral-type mucosa (84%) or IM (13%) at the incisura angularis, compared to uninfected patients (18% and 3%, respectively).<sup>120</sup> In another study, IM was found in 6% of patients at the incisura, suggesting that sampling of this area should always be included in the assessment of patients with chronic gastritis.<sup>121</sup> The Updated Sydney Protocol may miss the presence of IM in more than 50% of cases.<sup>118</sup>

#### Autoimmune Atrophic Metaplastic Gastritis

Autoimmune atrophic metaplastic gastritis (AMAG) preferentially affects the gastric corpus and typically spares the gastric antrum.<sup>122,123</sup> AMAG preferentially affects older patients and women, and is associated with other autoimmune disease.<sup>124,125</sup> AMAG predisposes to pernicious anemia and confers an increased risk for development of hyperplastic and dysplastic polyps, carcinoma, and endocrine tumors.<sup>126</sup> AMAG is associated with serum auto-antibodies, including anti-intrinsic factor and anti-parietal cell antibodies.<sup>127</sup> AMAG does not cause specific clinical manifestations until a critical decrease has occurred in the parietal cell mass, beyond which anemia develops.<sup>128</sup> Years before the

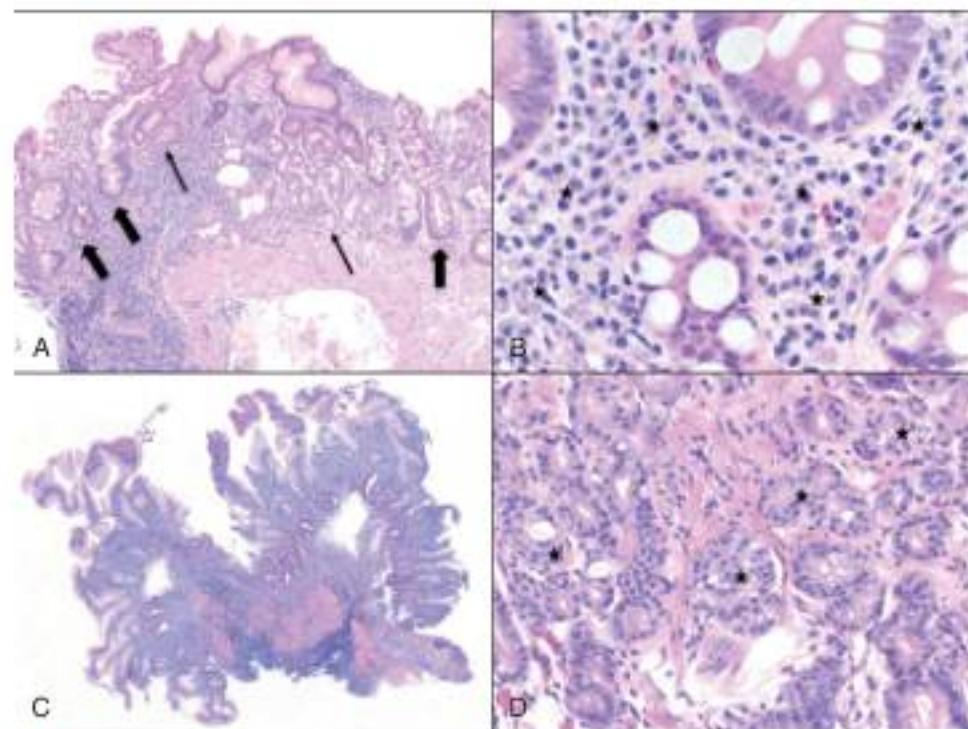

onset of anemia; patients may show various degrees of hypochlorhydria, hypergastrinemia, and loss of pepsin and pepsinogen secretion.<sup>123</sup>

Endoscopically, the mucosa of the corpus in patients with autoimmune gastritis is usually thinner than normal and shows a reduction or complete absence of rugal folds. Fine submucosal vessels are usually easily recognizable on endoscopic examination in advanced cases. Hyperplastic polyps are also common in advanced-stage disease. Polyps are detected in 20% to 40% of patients with pernicious anemia; they are mostly sessile, less than 2 cm in diameter, and often multiple. Most are hyperplastic, but as many as 10% contain foci of dysplasia. Gastric cancers associated with pernicious anemia are mostly intestinal type and arise from IM, suggesting that carcinoma in autoimmune gastritis likely develops through a metaplasia-dysplasia-carcinoma pathway.<sup>126</sup>

Microscopically, the main pathologic features of uncomplicated autoimmune gastritis are diffuse corpus-restricted chronic atrophic gastritis with some degree of IM and enterochromaffin-like (ECL) cell hyperplasia (Fig. 5.8).<sup>123</sup> In the absence of comorbidities, such as concurrent HP infection or bile reflux, the antrum is typically normal. This pattern of involvement is characteristic of patients with advanced disease and is found in patients with pernicious anemia. Three pathologic phases can be identified during the course of autoimmune gastritis in corpus mucosa: early, florid, and end stage.<sup>123,124</sup> The early phase is characterized by diffuse or multifocal, dense lymphoplasmacytic infiltration; IM and oxytotic gland destruction may be patchy in the early

stage and the possibility of sampling error limiting the diagnostic yield of biopsies exists. The florid phase of autoimmune gastritis is characterized by marked atrophy of oxytotic glands, prominent pseudopyloric and IM, diffuse lymphoplasmacytic inflammation, and normal or reduced thickness of the mucosa. At this stage of the disease, the pathologic features of autoimmune atrophic gastritis are sufficiently distinctive, particularly if the antrum is normal. However, demonstration of antibodies directed against parietal cell and intrinsic factor antigens is necessary for confirmation.<sup>127,128</sup> The end stage of disease is characterized by a marked reduction in oxytotic glands, foveolar hyperplasia, hyperplastic polyp formation, and increasing degrees of pseudopyloric, pancreatic, and IM. At this stage, parietal cells are difficult to detect, and inflammation is usually minimal or absent, although scattered lymphoid aggregates may persist.

During the florid and end stages, ECL cell proliferation is prominent, as a result of achlorhydria and hypergastrinemia. ECL cell carcinoids may arise during the florid phase and they are found most commonly in patients with end-stage disease.<sup>125,126</sup> Carcinoid tumors associated with ECL cell hyperplasia occur in 5% to 8% of patients with autoimmune gastritis and severe hypergastrinemia, and they account for 70% to 80% of all gastric carcinoid tumors.<sup>129</sup> ECL cell proliferation is not unique to autoimmune gastritis and may also occur in patients with Zollinger-Ellison syndrome, multiple endocrine neoplasia syndromes, and HP-associated, multifocal atrophic gastritis. Carcinoid tumors in patients with autoimmune gastritis are relatively innocuous and are associated with a more than a

**FIG 5.8** **A**, Representative biopsy from the stomach of a patient with autoimmune gastritis showing complete oxytotic gland atrophy, pseudopyloric metaplasia (thin arrows) and intestinal metaplasia (thick arrows). Also present is a prominent lymphoplasmacytic infiltrate in the lamina propria (**B**, lamina propria plasma cells highlighted by stars). Hyperplastic polyps (**C**) and neuroendocrine cell hyperplasia (**D**, highlighted by stars) are also manifestations of this disease.

95% 5-year survival rate, which sharply contrasts with the less common solitary, sporadic type of carcinoid tumors that are biologically more aggressive (< 35% 5-year survival rate).<sup>133</sup> It is important to convey to clinicians the clinical and pathologic context in which a gastric carcinoid is diagnosed.

Biopsy remains an important component of AMAG diagnosis and histologic exam is considered a reliable method of diagnosis. There are no standardized endoscopic mucosal biopsy protocols for AMAG.<sup>132,133</sup> The updated Sydney system is recommended: two biopsies from the corpus, two from the antrum, and one from the incisura angularis.<sup>137</sup> To establish a diagnosis of AMAG, biopsies from the antrum and body should be submitted in separate jars for independent assessment of each anatomic site, which aids in identification of the preferential gastric corpus atrophy. Biopsies should also be directed at ulcers, nodules, polyps, and masses to rule out neoplasia; these targeted biopsies should be submitted in separate jars.

### Intestinal Metaplasia

IM is occasionally detected in the stomach of patients without a documented history of autoimmune gastritis or HP gastritis (see Fig. 5.7A, C). IM is defined as the replacement of gastric-type mucinous epithelial cells with intestinal type cells, including goblet cells and enterocytes.<sup>136</sup> IM develops in a variety of pathologic settings and usually indicates the presence of chronic atrophic gastritis, which can occur in the setting of HP gastritis. The development of extensive IM in this scenario is termed *environmental metaplastic atrophic gastritis* (EMAG). In the absence of a complete set of biopsies from different anatomic areas of the stomach, use of a well-defined biopsy sampling protocol (such as updated Sydney system) is considered the minimum required for reliable staging of chronic gastritis. Tissue sampling in EMAG is performed to establish the diagnosis, to define the etiology and anatomic distribution of disease, and to evaluate for the presence and extent of dysplastic or neoplastic change. The stage of gastritis is determined by the combination of the extent of atrophy (scored histologically) with its topographic location (resulting from the mapping protocol). There is no standard biopsy protocol for the diagnosis and surveillance of EMAG. In a prospective, multicenter study of 112 patients with gastric IM or dysplasia, a regimen consisting of at least 12 biopsy samples had 100% sensitivity for the diagnosis of EMAG, dysplasia, and cancer, whereas one regimen consisting of seven nontargeted biopsies was able to diagnose IM in 97% of cases and all cases of dysplasia or cancer.<sup>138</sup> In contrast, the updated Sydney protocol detected 90% of cases of known EMAG, but also failed to identify 50% of patients with dysplasia or gastric cancer.<sup>137</sup>

Patients with EMAG may be at higher risk for developing dysplasia and carcinoma.<sup>139,140</sup> High-risk patients include those with a family history of gastric cancer, Hispanics, African-Americans, and immigrants from higher-risk geographic locations. Some studies have reported an 11% risk of adenocarcinoma for patients with atrophy or IM during a 10-year follow-up period.<sup>141,142</sup> No formal recommendations or data exist to support the implementation of an endoscopic surveillance program in high-risk patients who have gastric IM. Patients who have dysplasia and IM have a 100-fold increased risk of carcinoma.<sup>142</sup> There is no consensus regarding the appropriate time interval or biopsy surveillance protocol after a diagnosis of LGD of the stomach. Studies have suggested that in a patient with EMAG, topographic mapping of the gastric mucosa should be performed

every 3 months during the first year, followed by repeated surveillance endoscopy every 3 years if extensive metaplasia persists, along with sampling of any endoscopically visible lesions.<sup>143,144,145-148</sup> The American Society of Gastrointestinal Endoscopy (ASGE) recommends that patients with confirmed HGD on gastric biopsies be considered for gastrectomy or EMR.<sup>146,148</sup>

### Gastric Polyps

Gastric epithelial polyps include fundic gland polyps, hyperplastic polyps, and adenomas. Gastric polyps are often incidentally detected on endoscopy. Polyp histology cannot be reliably distinguished by endoscopic appearance. Endoscopic forceps biopsy is inadequate to rule out dysplasia and carcinoma for polyps larger than 0.5 cm to 1 cm. Hyperplastic polyps are most common, and often occur in the setting of chronic gastritis (see Fig. 5.8C).<sup>147,148</sup> Fundic gland polyps that develop sporadically or in association with long-term PPI use have very low to no malignant potential.<sup>149</sup> It should be realized, however, that dysplasia may be found in fundic gland polyps associated with familial adenomatous polyposis.<sup>150</sup> Dysplastic elements may be present in as many as 20% of hyperplastic polyps.<sup>151</sup> Adenomatous gastric polyps also have malignant potential. Hyperplastic and adenomatous polyps may occur in the presence of HP infection and EMAG, and sampling of these entities should be performed. When hyperplastic and adenomatous polyps are identified or suspected based on endoscopic appearance, biopsy samples should also be taken from the surrounding nonpolypoid mucosa to exclude dysplasia arising in a background of metaplastic atrophic gastritis, and to determine the cause and extent of the underlying inflammatory and dysplastic condition.

### Small Intestine

#### Celiac Disease

Celiac disease is an autoimmune-mediated disorder affecting genetically susceptible patients that results in damage to the proximal small-intestinal mucosa and of malabsorption of nutrients as a result of exposure to dietary gluten. Celiac disease may appear at any time in life, from early childhood to late adulthood. Celiac disease in adults represents a large, previously unappreciated disease population.<sup>152-154</sup> There has been a substantial increase in the rate of diagnosis over the last decade and celiac disease remains underdiagnosed in the United States.<sup>155,156</sup> It is recommended that patients suspected of having celiac disease based on clinical parameters should undergo testing.<sup>157</sup> Classic symptoms include abdominal discomfort, diarrhea, and steatorrhea.<sup>158,159</sup> However, some patients do not develop diarrhea, but instead, exhibit other signs and symptoms, including short stature, infertility, neurological disorders, recurrent aphthous stomatitis, or dermatitis herpetiformis.<sup>158-163</sup> In adults with occult celiac disease, fatigue and iron deficiency anemia are common, which ultimately prompt investigatory tests that uncover the correct diagnosis.<sup>164</sup> Some patients are entirely asymptomatic and present initially only with histologic changes on biopsy analysis ("latent celiac disease").<sup>152,153</sup>

No single serologic test for celiac disease has a perfect sensitivity or specificity. Immunoglobulin A (IgA) antitissue transglutaminase (TTG) antibody is the preferred initial single test for detection of celiac disease in individuals over the age of 2 years.<sup>157,158</sup> Serologic testing may be negative in up to 16% of patients, and if clinically indicated based on symptoms and evidence of malabsorption, additional testing should be pursued for confirmation.<sup>165,167</sup> Endoscopic examination and small bowel

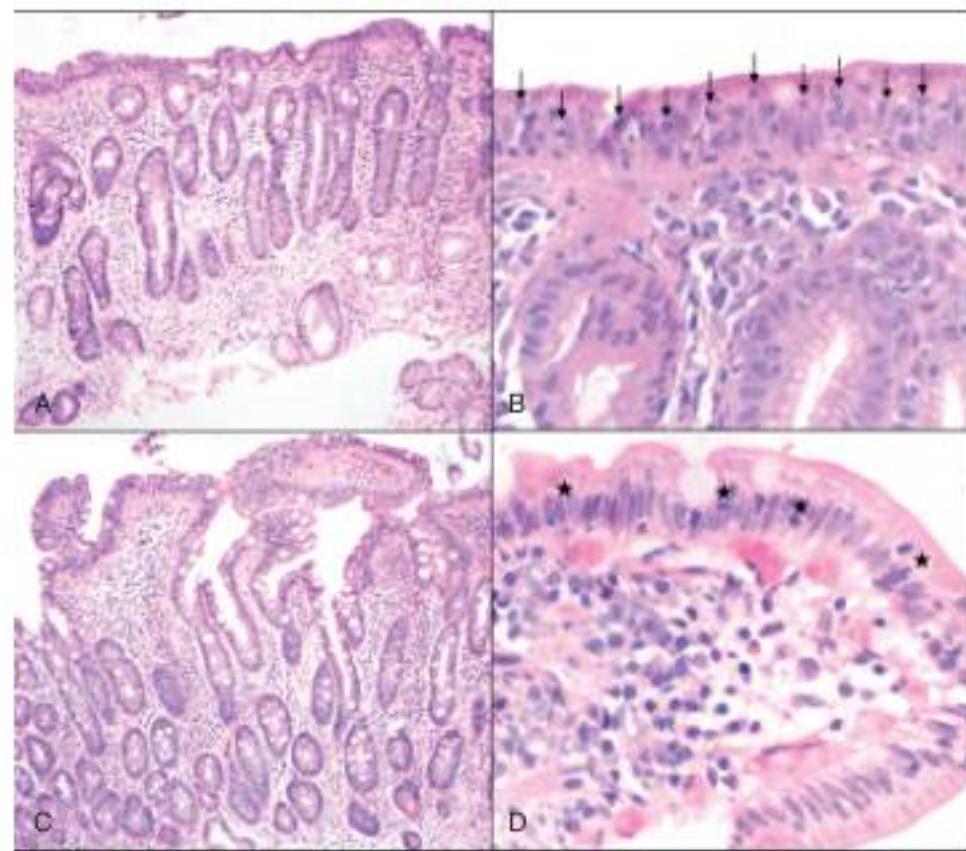

biopsy continue to play a critical role in establishing and confirming the diagnosis of celiac disease.

In patients with undiagnosed and symptomatic celiac disease, the endoscopic appearance may show classic features, characterized by a flat, scalloped appearance of the duodenum.<sup>106</sup> However, the endoscopic findings in patients with celiac disease can be subtle and often unreliable. One endoscopic study found that a reduction of folds, scalloping, mosaic pattern, and nodular mucosa were sensitive, but not specific, endoscopic findings in celiac disease, as they were also noted in some dyspeptic patients without celiac disease.<sup>107</sup> Similarly, a meta-analysis of studies testing the diagnostic sensitivity and specificity of video capsule endoscopy in celiac disease patients reports that the images seen can correctly diagnose the condition.<sup>108</sup> However, there is insufficient data on performance in mild histologic forms that are commonly seen.<sup>109,110,111,112</sup> Confocal laser microscopy shows promise as an endoscopic technique that can recognize villous irregularity and blunting, with the caveats that interobserver variability is high and the technique is not yet widely available.<sup>113</sup>

Histologically, the classic features of untreated celiac disease include complete villous atrophy, increased lamina propria chronic inflammation, and increased intraepithelial CD3+/CD8+ T-lymphocytes (Fig. 5.9). The histologic features of celiac disease are frequently classified according to Marsh, Marsh modified (Oberhuber), or simplified Corazza classification schema.<sup>114,115,116</sup>

Classic celiac disease shows greatest severity of histologic changes distally in the duodenum and proximal jejunum. The ileum may be involved in severe cases, but it is not a reliable site for biopsy diagnosis.<sup>108,113–117</sup> It is now widely recognized that many patients with celiac do not have diffusely abnormal duodenal histology, but instead show mild and patchy involvement in duodenal mucosal biopsies (see Fig. 5.9).<sup>118–122</sup> Ravelli et al (2001) prospectively evaluated 110 pediatric patients with elevated serum endomysial and/or tissue transglutaminase antibodies and clinical symptoms of celiac disease.<sup>123</sup> Each patient underwent mucosal biopsy of the duodenal bulb, proximal duodenum, intervening duodenum, and distal duodenum near the ligament of Treitz. Ninety-three percent of patients had changes compatible with celiac disease in at least one tissue sample, and 93% had similar findings in all samples. None of the patients had any tissue samples that were histologically normal, although complete loss of villous architecture was more commonly observed in samples from the distal small intestine. Some biopsies show preserved or minimally blunted villous architecture with a patchy increase ofIELs.

Celiac disease may also be localized to the duodenal bulb. The duodenal bulb is now a recommended biopsy site because it is reliably involved in patients with patchy disease.<sup>112,114</sup> In a pediatric study, 16% of children had patchy villous atrophy, but all of them had involvement of the duodenal bulb, and in four patients the bulb was the only site of abnormality.<sup>112</sup> Similarly,

**FIG 5.9** Biopsies of the duodenum from a patient with celiac disease showing variable involvement in different parts of the duodenum. In one area, complete villous atrophy along with increased intraepithelial lymphocytes is present (A and B, intraepithelial lymphocytes highlighted by thin arrows). A different portion of the duodenum shows preserved villi without significant increase of intraepithelial lymphocytes (C and D, occasional lymphocytes highlighted by stars).

Mooney et al (2016) described the features of ultrashort celiac disease limited to the duodenal bulb in a cohort of adult patients.<sup>185</sup> Duodenal bulb biopsies may also be more sensitive in patients following a low-gluten diet.<sup>186</sup> Further evidence supporting the validity of duodenal bulb biopsies as a diagnostic site is found in the study by Walker et al (2010), in which paired IEL counts were identical in the duodenal bulb and second duodenum in patients with celiac disease.<sup>187</sup> However, duodenal sampling had no effect on increasing detection of celiac disease in a low pretest probability cohort.<sup>188</sup>

Multiple samples taken from different sites of the duodenum are thought to help avoid inadequate sampling as a result of variable involvement of the disease, biopsy crush artifact, and allow for proper specimen orientation (Table 5.2). Based on studies in both adults and children, it appears that the most reliable biopsy protocol to detect all cases of celiac disease is a three- (or preferably five-) biopsy regimen that includes the duodenal bulb, the proximal duodenum, and the distal duodenum (see Table 5.2).<sup>178,182,184,189</sup> Although endoscopically abnormal mucosa should be preferentially targeted for sampling, it is important to realize that histologic disease may underlie normal-appearing mucosa. Historically, it was thought that well-oriented biopsy samples made it easier for pathologists to identify the cardinal features of celiac disease. Recent data, however, suggest that patients with celiac disease may only show increased intraepithelial lymphocytosis (as opposed to villous atrophy) as the key diagnostic finding.<sup>190</sup> Increased intraepithelial lymphocytosis is a feature that does not rely heavily on specimen orientation.

Refractory sprue is defined as a lack of or incomplete clinical response to a gluten-free diet.<sup>191–193</sup> Most patients with refractory sprue have histologic abnormalities similar to untreated celiac disease. However, some refractory sprue patients show loss of markers in the intraepithelial T-lymphocytes, or even monoclonality of the T cells. Collagenous sprue, characterized by a thickened subepithelial collagen layer, has since been reported in several series as a pattern of injury seen in the setting of refractory sprue, as well as associations with angiotensin receptor blockers.<sup>191,194,195</sup>

## Colon

### Inflammatory Bowel Disease

Inflammatory bowel disease (IBD), comprising ulcerative colitis (UC) and Crohn's disease, is a very common inflammatory bowel disorder affecting almost 1.5 million patients in the United States.<sup>196</sup> A diagnosis of IBD is established by a combination of clinical presentation and history, laboratory values, typical endoscopic features, histologic evaluation of mucosal biopsies, and radiologic findings.<sup>197</sup> The mucosal biopsy initial presentation is an integral component of IBD diagnosis. Microscopically, IBD mucosal biopsies, in both UC and Crohn's disease, show features of chronic colitis, including basal plasmacytosis, basal lymphoid aggregates, Paneth or pyloric metaplasia, and crypt distortion. Distinguishing between UC and Crohn's disease is based largely on the pattern and distribution of disease, rather than specific histologic features. If detected, the presence of granulomas favors Crohn's disease.<sup>198</sup> These histologic features are not entirely specific for IBD and might be found in other disorders, for example, IBD-like ischemia, radiation colitis or drug colitis.<sup>199</sup> After initiation of treatment, IBD biopsies may show mucosal healing.<sup>200</sup> The pathologist's role in evaluating IBD biopsies regardless of the temporal relationship to treatment, is to evaluate pathological extent of disease, degree of activity, and the presence or absence of dysplasia or cancer.

Biopsy protocols to diagnose, stage, and survey patients with IBD are based on expert consensus, case series, case-control studies, population-based cohort studies, prospective studies, and, in the case of optimal technique for surveillance colonoscopy, controlled trials (see Table 5.2).<sup>201,202</sup> Initial diagnosis of IBD should include confirmatory biopsy samples, to exclude the presence of other etiologies, such as infection. In patients undergoing ileocolonoscopy for suspected IBD, at least two biopsy samples should be taken from five sites, including the ileum and rectum, during the initial endoscopic evaluation. Specimens should be taken of both diseased and adjacent normal-appearing mucosa.<sup>202</sup> In a study of 414 consecutive patients who underwent intubation and biopsy of the terminal ileum, it was found that the diagnostic yield of ileal biopsies was highest in patients with suspected Crohn's disease, abnormal imaging studies, or endoscopic findings, but ileal sampling was not helpful when the endoscopic appearance of the ileal mucosa was normal.<sup>203</sup> The biopsy specimens from different locations should be separated in different jars to allow for evaluation of the extent and severity of disease. Higher detection rates for granulomas can be achieved when biopsy specimens are taken from the edge of ulcers and aphthous erosions.<sup>204,205</sup> If an EGD is performed for clinically suspected upper GI tract IBD, at least two biopsy samples should be taken from the esophagus, stomach, and duodenum.<sup>205,206</sup>

Surveillance for colorectal cancer is recommended for patients with long-standing IBD, particularly 8 to 10 years after onset of disease (see Table 5.2).<sup>207,208</sup> Although less common than UC,

**TABLE 5.2 Recommendations for Optimum Location and Number of Mucosal Biopsies for Evaluation of Common Gastrointestinal Disorders of the Lower Gastrointestinal Tract**

Disease	Location and Number of Biopsy Samples
Microscopic colitis <sup>200</sup>	Two or more biopsies each from the transverse, descending, and sigmoid colon Additional sampling of endoscopically visible abnormalities
Inflammatory bowel disease <sup>201,202,203,204,205</sup>	Surveillance for dysplasia: Thirty-three random samples from patients with pancolitis, including five to six samples each from the right, transverse, distal, and sigmoid colon, proximal and distal colon, or four-quadrant biopsies per 10 cm of colitic mucosa, and four-quadrant biopsies per 5 cm of colitic rectal mucosa if dysplasia is present; Complete removal of endoscopically resectable lesions, to include tissue sampling from mucosa surrounding the resection site to confirm complete excision
Graft versus host disease <sup>206</sup>	Optimal approach yet to be determined. Consider biopsies from upper and lower gastrointestinal tract. Avoid rectum only biopsies.

extensive colitis secondary to Crohn's disease also carries an increased risk for cancer. Data obtained from a cohort of 692 patients with IBD indicate that the standardized incidence ratio of colorectal carcinoma among Crohn's disease patients is 1.9, compared to 2.4 for patients with UC.<sup>209</sup> Colitis-related dysplasia may be present in endoscopically flat mucosa, or it may grow as a polyp, nodule, ulcer, or plaque. Studies indicate that most dysplasia is endoscopically visible.<sup>210-212</sup> Current surveillance strategies recommend extensive sampling of colonic mucosa and raised lesions, ulcers, or other suspicious areas. A study of 101 UC patients, including 81 high-risk and 20 low-risk patients, found that at least 56 jumbo-sized, nontargeted mucosal biopsies were necessary to exclude the possibility of dysplasia. This observation has led to the common practice of obtaining multiple tissue samples from every 10 to 12 cm of colon, or, alternatively, five to six samples each from the right colon, transverse colon, descending colon, sigmoid colon, proximal rectum, and distal rectum.<sup>213</sup> Several professional societies have proposed more recent surveillance protocols that vary slightly with respect to the time at which screening is performed following a diagnosis of colitis, the interval between surveillance examinations, and the number and location of tissue samples procured.<sup>143,197,214-215</sup> For instance, the ACG recommends that surveillance commence 8 to 10 years after the initial diagnosis of colitis and be repeated every 1 to 2 years with multiple biopsy samples obtained from every 10 cm of colon, regardless of the extent of colitis.<sup>214</sup>

The SCENIC international consensus statement, published in 2015, summarizes the evolving evidence of newer endoscopic methods for surveillance and management of dysplasia in IBD patients.<sup>216,217</sup> In the SCENIC statement, lesions are described according to a new nomenclature, which replaces the term *dysplasia associated lesion or mass* (DALM) and recommends using descriptive terms modified from the Paris Classification of neoplastic lesions of the gut.<sup>218</sup> Visible dysplasia is classified as polypoid or nonpolypoid. In addition, the term *endoscopically resectable* was defined to indicate that the lesion margins could be identified, the lesion appears to be completely removed on visual inspection, histologic examination of the specimen is consistent with complete removal, and biopsies taken from mucosa immediately adjacent to the resection site are free of dysplasia. This is a paradigm shift that has important implications for the surveillance and management of dysplasia.<sup>219</sup>

To optimize detection of dysplastic changes when using standard white light endoscopy, chromoendoscopy by using methylene blue or indigo carmine with targeted biopsies is recommended when expertise in this technique is available.<sup>143,197</sup> The SCENIC recommendations place the emphasis on chromoendoscopy for high-quality visual inspection of the mucosa.<sup>216,217</sup> A meta-analysis of prospective studies comparing chromoendoscopy with standard white light endoscopy found chromoendoscopy is significantly better in detecting dysplasia in patients with colonic IBD.<sup>220</sup> When chromoendoscopy is not available, especially if there is extensive active disease, significant pseudopolyposis, or poor preparation, random mucosal sampling with targeted biopsies of any suspicious-appearing lesions remains a reasonable alternative. In patients with documented pancolitis, biopsy specimens should be obtained in a four-quadrant fashion every 10 cm from the cecum to the rectum for a minimum of 33 total random mucosal samples in an attempt to detect dysplastic changes.<sup>211</sup> In patients with less extensive colitis, biopsy specimens can be limited to the greatest extent of endoscopic or histologic involvement documented by any colonoscopy. Because

of an increased risk of colorectal cancer in the rectum and sigmoid, sampling every 5 cm in the distal colon should be considered.

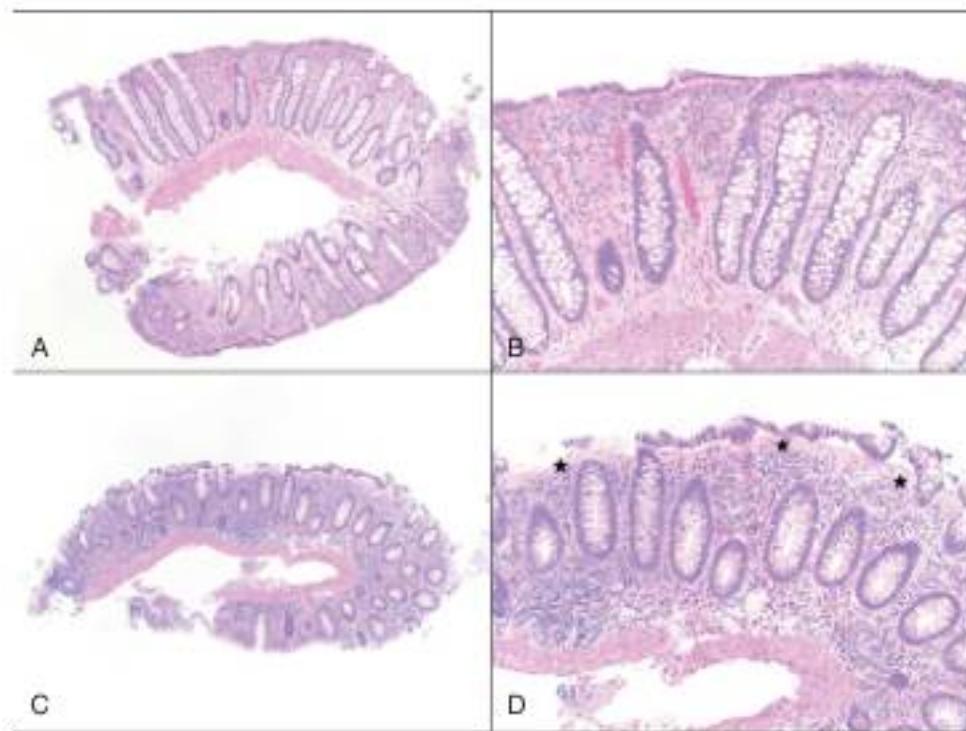

During colonoscopy, targeted biopsies of all visible abnormalities should be performed. Lesions should be described accordingly using the new classification and resections should be performed for endoscopically resectable lesions. According to the SCENIC recommendations, all lesions that appear endoscopically resectable should be removed in their entirety, and biopsy specimens of the flat mucosa surrounding the resection site should be obtained to ensure that the lateral margins are free of dysplasia.<sup>214,216,217</sup> The endoscopically removed lesion and the flat mucosa sample from the surrounding resection site should be placed in separate specimen containers and submitted for histologic confirmation of complete removal. After complete removal of endoscopically resectable dysplastic lesions, surveillance colonoscopy is recommended rather than colectomy. In patients who have endoscopically invisible dysplasia confirmed by a GI pathologist, referral to an endoscopist with IBD expertise is also recommended.

### Microscopic Colitis

Microscopic colitis refers to autoimmune disorders characterized by chronic, watery, nonbloody diarrhea in patients with normal endoscopic features, but with evidence of histologic inflammation in their colonic biopsies.<sup>221</sup> There are two types, collagenous colitis and lymphocytic colitis. Patients are diagnosed in late adulthood, but young adults and even children may be affected.<sup>221</sup> Women are more commonly affected than men; the female-to-male ratio ranges from 3:1 to 9:1 in cases of collagenous colitis and slightly lower in lymphocytic colitis (F : M ratio between 2.4:1 and 2.7:1).<sup>221</sup> Affected patients have significant associations with other autoimmune disorders, including autoimmune thyroiditis, rheumatoid arthritis, and celiac disease, among others.

Most patients with microscopic colitis have a normal-appearing colon. Patchy erythema, edema, friability, an abnormal vascular pattern, and even frank ulcerations may occur in a small minority of patients. Some cases show pseudomembranes and linear mucosal breaks ("cat-scratch colon"). The mucosa in collagenous colitis, more so than in lymphocytic colitis, is prone to endoscope trauma and even perforation, thought to be caused by barotrauma as a result of insufflation of air into the colon at the time of endoscopy, combined with the endoscope trauma.<sup>224-226</sup>

Collagenous colitis and lymphocytic colitis have some overlapping histologic features. These include preservation of crypt architecture combined with an increase in inflammatory cells within the lamina propria, especially in the superficial half, and degeneration of the surface epithelium. Inflammatory cells include lymphocytes, plasma cells, and eosinophils. Eosinophils are more numerous and prominent in cases of collagenous colitis than in lymphocytic colitis. The pathognomonic finding of collagenous colitis is the presence of a thickened or irregular subepithelial collagen layer, which is usually thicker than 10 µm.<sup>227</sup> Collagen thickening may be continuous or patchy in distribution. Lymphocytic colitis lacks a thickened collagen layer. In lymphocytic colitis, there are increased IELs, typically greater than 20 per 100 surface epithelial cells.<sup>228</sup> Some cases of lymphocytic colitis show minimal histologic changes and only a slight increase in intraepithelial lymphocytosis ("atypical," "paucicellular," or "minimal change" lymphocytic colitis). In these mild cases, the disorder produces a mild increase in lamina propria inflammatory cells, usually limited to the superficial half of the mucosa. IELs are also seen in collagenous colitis; however, the degree of intraepithelial lymphocytosis is less than in lymphocytic colitis.

**FIG 5.10** Patient with collagenous colitis with variable involvement of the colon. Rectum (**A** and **B**, low and high power respectively) showing no significant involvement compared to the right colonic biopsies (**C** and **D**, low and high power respectively) with extensive thickening of the subepithelial collagen layer (stars mark the thickened collagen), increased inflammation in the lamina propria and prominent surface epithelial cell detachment.

The pathologic features of microscopic colitis may be patchy and focal (Fig. 5.10).<sup>238</sup> Several studies have shown more severe involvement of the right versus the left colon. Rectal sparing has been observed in as many as 8% of cases.<sup>239</sup> No consensus exists for the optimal method of mucosal sampling in suspected microscopic colitis. Data suggest that a substantial number of patients with unexplained chronic diarrhea benefit from colonoscopy and mucosal biopsy analysis (see Table 5.2).<sup>231–233</sup> The potential patchy distribution of microscopic colitis sometimes requires biopsy of the right and transverse colon, in addition to the left side of the colon, for diagnosis.<sup>239,254,255</sup> A reasonable initial strategy may be to proceed with either flexible sigmoidoscopy or colonoscopy, with two or more biopsy samples taken from three or four areas of the colon. In situations in which flexible sigmoidoscopy is nondiagnostic, but clinical suspicion for microscopic colitis remains high, colonoscopy with additional mucosal sampling from the proximal colon should be considered. No formal comparative effectiveness analysis exists comparing and evaluating the two strategies.

#### Graft Versus Host Disease

Graft versus host disease (GVHD) is one of the most common complications following hematopoietic stem cell transplantation and develops in as many as 50% of patients.<sup>236</sup> The GI tract is commonly involved and manifests with various signs and symptoms, including nausea, vomiting, anorexia, profuse diarrhea, or ileus.<sup>237</sup> The diagnosis of GVHD in the GI tract is made through a combination of clinical and laboratory features, along with exclusion of other causes of GI tract dysfunction. Endoscopic biopsy and histologic examination is an important component

for assessment of patients presenting with digestive symptoms in the posthematopoietic stem cell transplant period.

The endoscopic appearance of GI GVHD is variable, ranging from mucosal edema and erythema to more severe changes of ulceration or mucosal sloughing; however, endoscopic findings do not correlate well with histologic findings.<sup>238</sup> Microscopically, the major histologic feature of GVHD is the presence of epithelial cell apoptosis and relatively sparse mononuclear cell infiltrate.<sup>236,240</sup> In more severe examples, crypt loss and destruction are also seen. A grading scheme for GVHD has been proposed; however, correlation with clinical symptoms, endoscopic findings, and patient outcome is poor.<sup>241,242</sup> The histologic changes of GI GVHD are not entirely specific, and disorders such as infection, drug-related injury (in particular mycophenolate mofetil), ischemia and, rarely, IBD are part of the differential diagnosis.<sup>243</sup>

GVHD can affect any part of the GI tract. The optimal diagnostic approach for GI acute GVHD has yet to be determined, and studies on this topic are limited. In many centers, site of biopsy depends on clinical experience among hematologists and gastroenterologists in assessment of this disorder. Discordant findings between the upper and lower GI tract have been reported.<sup>244</sup> Three small, prospective studies identified rectal or distal colon biopsy as the most sensitive test for the diagnosis of GI GVHD, even in patients presenting with primarily upper GI symptoms.<sup>245–247</sup> However, rectal biopsies alone can potentially miss up to 38% of GI GVHD cases.<sup>248</sup> One prospective study of 24 patients who had undergone stem cell transplantation identified EGD with sigmoidoscopy or ileocolonoscopy alone as equivalent strategies for the diagnosis of GVHD.<sup>247</sup>

## INTRODUCTION

The therapeutic basis of all electrosurgery is the use of high frequency, alternating electric current to produce heating in living cells. The heating can be manipulated to achieve a desired tissue effect such as cutting, tissue ablation, desiccation, or a combination of these. Electrical energy to produce heating and tissue effects has been a part of endoscopy since the early 1970s.<sup>1,2</sup> Common indications include biliary sphincterotomy, polypectomy, hemostasis, and the ablation of vascular lesions of multiple origins. Incorrect use of electrosurgery may contribute to poor patient outcomes such as post-polypectomy serositis, perforation, immediate or late hemorrhage, and sphincterotomy-associated complications.

Generator manufacturers give guidance as to suggested settings and output choices for various procedures. However, because there are many patient and physician technique variables that are outside of the manufacturer's knowledge regarding the generator's eventual impact, there can be no one "magic" setting that is guaranteed to always produce a known result. This is why physician discretion and knowledge remains important.

A clinician with no electrosurgical cognitive competence may be unable to troubleshoot, make appropriate alternate output selections, or be flexible in unusual situations. Without a good understanding of electrosurgical technology, it will be more difficult for a physician to expand his or her own clinical expertise into more advanced procedures such as endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD). Clinical understanding of the fundamentals of the technology is known to promote better patient outcomes.

From the clinician's point of view, this understanding and competence has been hampered by problems with nomenclature, lack of standardized training, inappropriate marketing messages,

and the perpetuation of incorrect understandings and/or outdated beliefs. All these have conspired to make electrosurgery "the most commonly used, but most often misunderstood technology."<sup>3</sup>

There is a lack of uniformity in names for output selections used by different manufacturers (Table 6.1). Similar names may have either similar or different characteristics from one manufacturer's generator to another. The terms themselves may be intuitively misleading. For example, a waveform may be called COAG but is very capable of cutting tissue. Some terms in common usage are manufacturer trademarks. SoftCoag refers specifically to an Erbe Elektromedizin GmbH (Tübingen, Germany) generator output, whereas TouchSoft is registered to Genii, Inc. (St. Paul, MN) for a technically equivalent, very low voltage output. The constant misuse of other terms such as electrocautery add to the confusion and seems particularly out of step with medical practice, which relies on precise terminology in everything from reporting diagnoses (diverticulosis is not diverticulitis) to recording methodologies for others to reproduce. Recently, both the *Journal of Minimally Invasive Gynecology*<sup>4</sup> and the journal *Gastrointestinal Endoscopy*<sup>5</sup> have addressed this issue and begun to promote standardization of terms. As far as possible, this chapter conforms to these new guidelines.

This chapter outlines the basic principles of electrosurgery pertaining to flexible endoscopy and attempts to relate the fundamentals of the technology directly to common and emerging clinical procedures. The use of proprietary or brand-specific terms is minimized, and only the most reliably referenced and up-to-date information to date is included.

## FUNDAMENTAL PRINCIPLES OF ELECTROSURGERY

Early pioneers of electrosurgical devices discovered that applying an electrical current to biologic tissue produces different effects.

**Abstract**

Electrosurgery uses high-frequency energy to create cellular heating and is a fundamental technology used in therapeutic flexible endoscopy. The heating effect can be manipulated to encourage a predominantly cutting or coagulating effect, and the balance between the two is the product of multiple variables. Variables can be patient or physician technique dependent; some depend on output selections made on an electrosurgery generator and the accessories attached to it. Much misunderstanding exists about the technology and its clinical use. This chapter uses accurate terminology, clear descriptions, and the best available science to clarify, enlighten, and encourage physician understanding of this important topic.

Genii and TouchSoft are US Registered Trademarks of Genii, Inc., St. Paul, MN. VIO, EndoCut, Swift Coag and SoftCoag are Trademarks of Erbe Elektromedizin GmbH, Tübingen, Germany. BiCap and Beamer are Trademarks of ConMed Corporation, Utica, NY. All information taken from Operator's Manuals.

Modified from Menna ML, Boavers WJ: Myth and the fundamentals of electrosurgery. *J Hepatol Gastroenterol* 1(1):1-5, 2016.

The first effect is electrolytic. Charged molecules in tissue flow toward opposite electrode poles if the current applied is direct or alternates slowly. Alternating the current more rapidly eliminates the electrolytic effect and produces heating at a cellular level. However, a current alternating at less than 100 kHz results in undesired neuromuscular effects. The shocking result of applying a household current of 60 Hz is well known. Alternating at a very high frequency (300 kHz) nearly eliminates neuromuscular effects but retains the desired cellular heating. This thermal effect is the basis of all electrosurgery.<sup>6</sup> Because this frequency is in the AM radio range, this energy is often referred to as *radio frequency* (RF), and a radio frequency electrosurgical generator is an acceptable term for an electrosurgical generator unit (ESU).

High-frequency alternating current is generated by an ESU and delivered to tissue via an assortment of suitable accessories. Water within cells heated very quickly vaporizes and causes the cell membranes to burst.<sup>7</sup> These bursting cells separate tissue. We use the accessory to guide the burst cells along a cleavage plane and say the tissue has been electrosurgically "cut."<sup>8</sup> Cells that heat more slowly dry out (coagulate) without bursting. The proportion of how many cells burst and how many coagulate, as well as how much tissue is involved, is referred to as the *tissue effect*. Many variables combine to make this end result (Fig. 6.1). Heating the tissue directly, producing both cutting and coagulation, sets electrosurgery apart from electrocautery. Because the intracellular water is heated directly by the RF energy and not by conduction from an already heated accessory, electrosurgery should never be referred to as *cautery*. Cautery devices produce coagulation by the passive transfer of heat from a heated accessory and can never produce electrosurgical cutting. This is why it is incorrect to use the term *electrocautery* for RF technology. True

cautery devices found in gastroenterology practices include the Olympus Heat Probe (Olympus Corp., Tokyo, Japan).<sup>9</sup>

### Variables That Impact Tissue Effect, Microprocessor Controls, and Waveforms

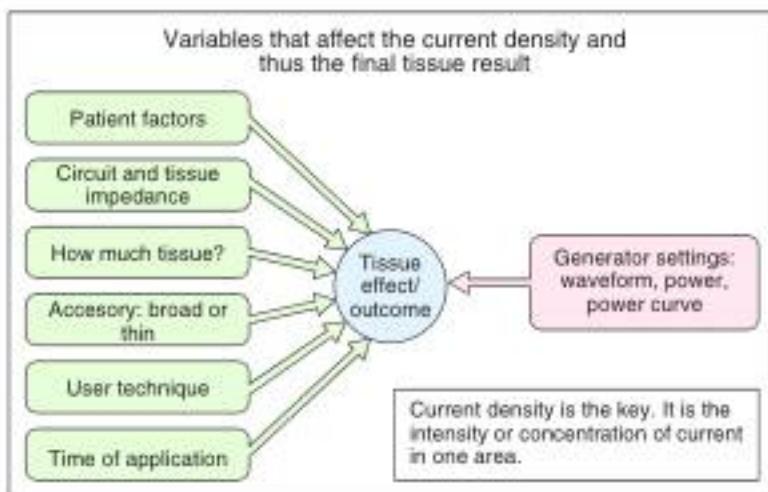

Current density is the defining variable in determining specific tissue effects in electrosurgery; yet it is the sum of the effects of all the other variables (see Fig. 6.1).

Current density is the measure of current concentration or, by definition, the current per unit area. The rate of heat generation, and therefore the resulting therapeutic effect, is a function of the current density. It is a measure of intensity. Mathematically, the temperature rises as a square of the current density. Current that will boil water on a square millimeter area will not even feel warm on a square-centimeter area.<sup>10</sup> The dramatic difference in surface area between the active electrode and the dispersive (grounding) pad is perhaps the best-known example of this principle. Current density depends on the applied voltage, current, and type of waveform, as well as the tissue impedance, the size of the electrode, and the time that current is flowing. Understanding the different characteristics of tissue heating under different circumstances is essential to understanding electrosurgery.

The physical law that relates all the electrosurgical variables is summarized by Ohm in the equation:

$$P = I^2 R$$

where  $P$  is power,  $I$  is current, and  $R$  is resistance (for our purposes, resistance and impedance are used synonymously). The  $P = V \times I$  derivation of this equation relates the type of waveform to total power ( $P$ ). Power combines both voltage ( $V$ ) and current ( $I$ ). For example, if power is to remain constant as voltage

**FIG 6.1** Current density variables. (Redrawn from Morris ML, Bowers WJ: Math, myth and the fundamentals of electrosurgery. *J Hepatol Gastroenterol* 1(1):1-5, 2016.)

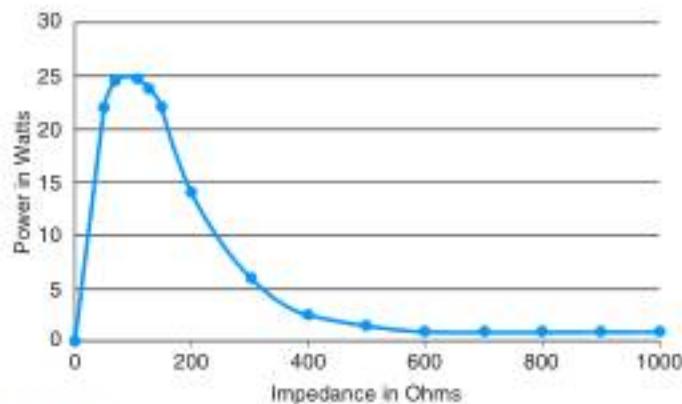

increases, then current must decrease. Ohm's Law defines another principle crucial to a clinical understanding of electrosurgery: as impedance in tissue rises, power (either current or voltage or both) decreases. If "nothing is done" as the therapy produces coagulation, and therefore the tissue impedance rises, the generator power must drop (*stall*).

To address this problem, research turned in the late 1980s to using microprocessors to measure and respond to changing impedance.<sup>11</sup> First patented in 1986, microprocessor monitoring allows an ESU to track a resistance baseline and subsequent changes in the resistance during the electrosurgical activation. Using millions of data points, the generator's software programming (algorithm) tells the generator how to regulate the current and/or voltage (which together form power) being delivered during the activation. A graphic representation of how a particular output is designed to react to changes in impedance is called a *Power to Impedance Curve* or *Power Curve*. Sometimes marketers will use the informal term *power dosing* to explain this. Power curves associated with each output selection are so important to understanding the operation of the ESU that regulatory bodies require these graphs to be included in every user manual.

Power to impedance curves tend to be either "narrow" or "broad." By convention, power is shown on the vertical axis with increasing resistance progressing to the right on the horizontal axis (Fig. 6.2). The horizontal axis is also likely to correlate with time as tissue resistance increases when tissue becomes coagulated with increasing time of application.

The power curve dictates that the power setting displayed on an ESU is not the power that will be delivered over the entire activation. Depending on the algorithm defining the curve, the power setting displayed may be a more or less close approximation of the actual or average power delivered, or simply a target maximum power. In all cases, the average power delivered will be less than the maximum or peak power delivered.

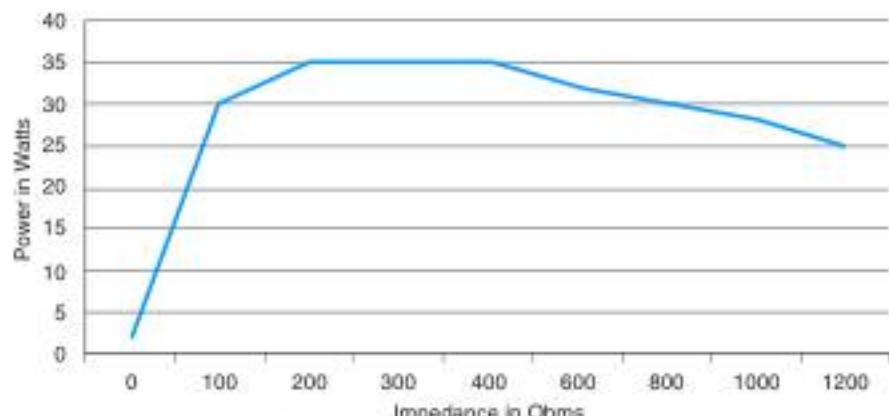

Outputs with narrow type power curves have been long utilized in flexible endoscopy for contact coagulation using very familiar bipolar endostasis probes. Matched with low-voltage continuous outputs and a narrow power curve, this bipolar method is a frequent and effective choice for hemostasis and control of bleeding.<sup>12</sup>

**FIG 6.2** A narrow power curve example (power displayed: 25 watts).

In Fig. 6.2, 25 watts have been selected by the user and will be displayed on the ESU. To the ESU's algorithm, this selected power represents only the maximum (or target) power to be delivered.<sup>13</sup> The ESU is programmed to ramp up quickly in the low-resistance situation characterized by frank bleeding. The target maximum is reached, but the power drops quickly as soon as the resistance reaches approximately 100 to 300 Ohms, which correlates well with the appearance of the characteristic whitish eschar, indicating adequate coagulation. This power curve delivers exactly what is desired: rapid onset of hemostasis with self-limiting depth of injury. With the low voltage of the output and this power curve, the tissue tends not to overly dry out, which would cause the bipolar accessory to stick. This well-matched output mode, power curve, and appropriate accessory provides the desired clinical effect of reliable and quick hemostasis.

A nearly identical narrow power curve and voltage cap, matched with monopolar accessories, is usually named SoftCoag (Erbe) or TouchSoft (Genii). These soft coagulation outputs are suggested for use with monopolar hot biopsy forceps (HBF) or newer monopolar contact coagulation accessories such as the Olympus Coagrasper or the Genii TouchSoft Coagulator. One study described successful use of a snare tip with a soft coagulation

**FIG 6.3** A broad power curve example.

output for touch-ups during the resection of large colonic lesions.<sup>14</sup> These monopolar counterparts do require the use of a return dispersive electrode (grounding pad) and require higher initial power settings to overcome the higher resistance in the monopolar circuit. TouchSoft or soft coagulation power maximums are usually set at 40, 50, or 60 watts versus the 15 to 25 watts that are very common for bipolar contact applications.

For snare polypectomy, sphincterotomy, or other procedures that depend on a smooth advance of an electrode, the narrow power curve would not be suitable, as stalling would result. Instead, a broad power curve (Fig. 6.3) where cutting with various levels of concurrent coagulation (depending upon the waveform and accessory selected) is the choice. These outputs usually ramp more slowly toward an effective power and maintain the effectiveness over a broad range of impedances. The result is a smooth and reliable transection. Again, in all cases the average power delivered over the activation will be less than the maximum or peak power. A marketing term called *constant power* is sometimes applied to broad curves but is mostly inaccurate. The power delivered is dynamically driven by the algorithm of the ESU as it responds to impedance/resistance measures. Rigid terms such as *constant*, *always*, and *never* are to be avoided in scientific and medical use for good reason. It is similarly not correct to refer to one entire ESU as a *constant power generator*. Every ESU in current use today has some outputs of both curve types included in its available selections. It is the physician's good understanding of the available outputs and their associated power curves that allow matching to suitable accessories to produce desired and optimal clinical results.

Broad power curves are ideal for most applications that require at least some cutting because the transection is done smoothly without stalling. The generator overcomes the Ohm's law directed drop in power by automatically adjusting the voltage and/or current to keep the cut progressing smoothly over a wide (broad) range of impedances. For ESUs intended for flexible endoscopy, it is now very common to also provide an additional microprocessor or software control layer over some of the broad curve output choices in order to interrupt or fractionate the cut. Named EndoCut (Erbe), Pulsed Cut (Genii), Pulsed Blend Cut (Genii), etc., these types of outputs have multiple options for adding more or less coagulation to the cutting advance. Multiple studies have shown a sole but important benefit of the pulsing or interruption of the advance: a significant reduction in uncontrolled or "zipper" cuts in sphincterotomy.<sup>15,16</sup>

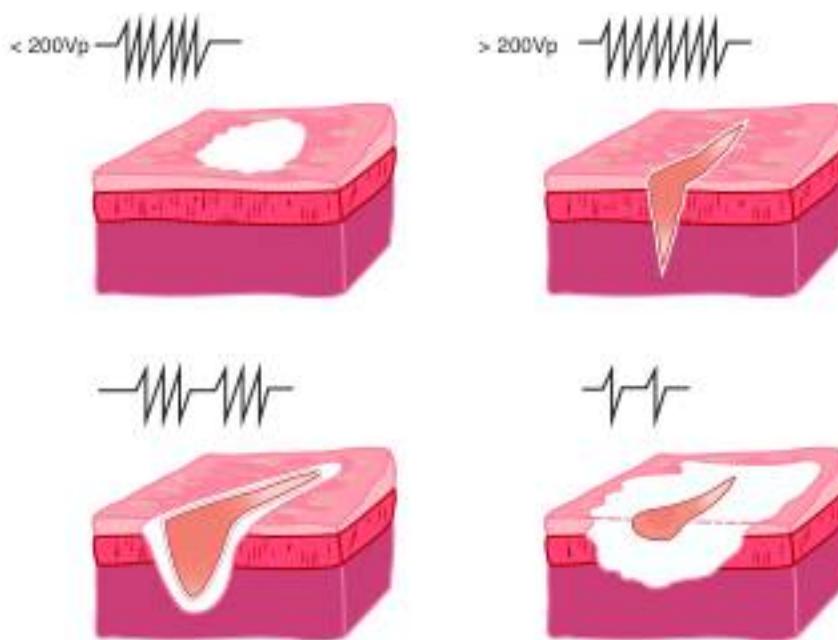

Microprocessor control on modern generators is very precise in reading dynamic impedance and holding current and/or voltage (power) changes tightly to the algorithm design demanded by the power curve.<sup>17</sup> For this reason, often the "watts" shown on the generator display may be absent or only an indication of a maximum power target. In any case, and with every power curve, the average power delivered over the total activation will be less than the peak power delivered. Often the generator requires a certain lag time to reach the programmed maximum power, may on occasion even slightly overshoot it, and will ramp down from the peak depending on the impedance. It is customary for record keepers to chart only the maximum selected power shown on the generator display.

As noted, the controlling concept of the final tissue effect is the current density at the treatment site. But many variables affect the current density. Some are under the physician's control, and some are not. Only a few are functions of the ESU (see Fig. 6.1).

A defining variable that is a selection on the electrosurgery generator is the high-frequency waveform, or output mode. In solid-state generators (the only type now produced), continuous sinusoidal waveforms with fairly low voltage increasingly give way to a higher-voltage waveform that is more and more interrupted (modulated) to take the tissue effect from one of mostly cutting to one of mostly coagulation (Fig. 6.4).

A continuous high-frequency waveform with a peak voltage of at least 200Vp will produce an intensity of current sufficient to create micro electric sparks between the active electrode and the target tissue. Such high-current density along the leading edge of the electrode causes cells to literally explode, separating the tissue as if it were cut. As this cell vaporization continues, a micro steam layer is formed, which helps to propagate the cutting effect.<sup>18</sup>

Along the edges of the cut, there will always be a margin of cells whose distance from the active electrode allows them to heat more slowly. These cells simply coagulate. This is why it is often said, "Only a cold cut is a pure cut." It is better to use the term *cut* rather than *pure cut*, but the literature does not yet reflect this new standard. The depth of the coagulated margin along the cut is related to the height of the peak voltage in the cutting waveform, with higher voltages leaving a thicker margin of coagulation. The coagulation margin is also influenced by the thickness of the electrode. A thin wire leaves less coagulation than a flat blade or a thicker endoscopic dissection wire or knife.

**FIG 6.4** Different waveforms produce different tissue effects.

Even with a continuous waveform, if the voltage never goes above 200Vp, no cutting can occur. Such outputs lack the intensity to initiate the initial sparking necessary to produce the cutting effect. A superficial coagulation results instead. These waveforms have been described earlier in the discussion about bipolar and monopolar soft coagulation output choices with narrow power curves.

To produce deeper thermal injury with less electrosurgical cutting and an increasingly greater proportion of coagulated cells, the continuous cut waveform is interrupted or modulated. Modulating the waveform delivers the energy, even at equivalent power settings, more slowly. To increase the depth of the coagulation, the voltage spikes are increased. This is necessary because along the margins of the electrode path, the impedance is rising as the tissue is coagulated. The higher voltage spikes force the current through the desiccated layer along the cut margin, increasing the depth of the coagulation.<sup>19</sup>

The modulated output that for a particular generator provides the deepest coagulation (hemostasis) with only some cutting may be named either *coag* or *forced coag*. Users often erroneously call these outputs *pure coag*. The term is erroneous because as long as the voltage spikes (at least sometimes) over 200Vp, some electrosurgical cutting is expected. This common but imprecise use of terminology can promote confusion. The most common coag waveform type (which often has approximately a 6% duty cycle and crest factor of approximately six) has been a first choice for polypectomy for decades; this is because the cutting action along the snare wire allows a clean transection, whereas the coagulation remaining promotes reliable hemostasis. With the advance of ESU technology offering a greater number of output choices on many ESUs, waveforms with a bit more cutting action and comparatively less thermal spread have gained nearly equal use. These waveforms may have names such as *blend coag* or *swift coag*.<sup>20</sup> Robust, evidence-based data as to what waveform should be preferred is currently absent. Therefore, an optimal guideline for waveform choice is not available, leaving this to the physician's discretion, preference, and experience.<sup>15</sup>

Many ESUs are equipped with a varying number of modulated waveforms that fall between the extremes of nearly all cut or nearly all coag. These are typically named the *blended currents*. This is perhaps the most descriptive name, as it correctly implies that some of the cells will be vaporized, or cut, whereas some will be coagulated. Increasingly modulated waveforms with increasingly high voltages will produce tissue effects with increasing hemostasis and decreasing cutting.

#### Methods for Quantifying Waveforms

The qualitative descriptions of waveforms can be quantified by assigning them a duty cycle or a crest factor. The duty cycle is the numerical percentage of the time the waveform is on (spiking) and the time it is off (interrupted). A waveform with a 6% duty cycle is on 6% of the time and off 94% of the total time. The common coag or forced coag types discussed previously are those with approximately a 6% duty cycle. Any continuous waveform has a 100% duty cycle. It will be the peak voltage that will determine if a 100% duty cycle waveform produces pure (intense) electrosurgical cutting or only soft coagulation. Crest factor is similarly used to quantify the degree to which a waveform is modulated, but is more informative for modulated waves in that it includes information about the peak voltage. Modulated waveforms with low duty cycles and high crest factors produce more and deeper coagulation than waveforms with low crest factors and high duty cycles (Table 6.2). Either duty cycle or crest factor information can be found in every generator's user manual.

A physician with a good knowledge of the principles of current density, the waveform choices on the ESU at hand, and its microprocessor controlled power curves is in a very good position to control, avoid, or compensate for all the other non-ESU variables that enter into the final tissue effect (see Fig. 6.1).

One of these non-ESU variables is the operator's technique, which includes the tension applied to the accessory. Some degree of tissue tension is necessary for progression of an incision (e.g., polypectomy or sphincterotomy). However, overzealous tension

\*Beamer Polyp Pulse Cut 1,2 and Papilla Pulse Cut 1,2 CF not available.

This table lists duty cycles and/or crest factors to aid endoscopists in quantifying different electrotherapy generator unit (ESU) modes. Each ESU will have additional waveform properties that contribute to tissue effect. Please refer to the operator's manual for each ESU or contact the manufacturer for further information.

Data published or provided by the manufacturers: Conmed Corp., Utica, NY; EndoStat distributed by Boston Scientific Inc., Natick, MA; Erbe USA Inc., Marietta, GA; Genii Inc., St. Paul, MN; Meditron, a division of Cooper Surgical, Trumbull, CT; Valleylab, Medtronic, Dublin, Ireland. Not all generators listed may be currently marketed.

may result in poor control of cutting, leading to a rapid incision with inadequate vessel coagulation and increased risk of hemorrhage. A slow advance can promote more coagulation. Highly skilled endoscopists performing ESD procedures are able to control small bleeding episodes simply by slowing the cut advance markedly. This holding staunches the bleeding with no change whatsoever in the accessory, the waveform output, or the power selection.

Resistance in an entire monopolar circuit or in the tissue itself varies before and during the incision. Highly fibrotic or scarred tissue is more resistant (and harder to cut) than tissue with a high water content. Tissue resistance is a dynamic variable that alters as tissue desiccates during the incision.<sup>21</sup> The entire resistance between an argon probe tip and the dispersive electrode plays a role in the length of the plasma arc that is generated during argon coagulation procedures. Blood flow is a variable that may help dissipate heat at the site of the tissue. Similarly, submucosal saline injection may act as a "heat sink" and help dissipate energy and prevent transmural injury during polypectomy and other procedures.<sup>22,23</sup>

### Monopolar and Bipolar Circuits

The most common method for completing the electrical circuit in gastroenterology procedures is to use a monopolar accessory and a remotely placed dispersive (grounding) pad. The current flows from the ESU and is concentrated at the treatment site by the accessory (e.g., a snare, sphincterotome, HBF, or needle-knife). The concentrated energy at the site has high current density which promotes tissue heating. The energy then flows through the patient's tissue following a path of least resistance to the dispersive electrode on the skin and hence back to the generator, completing an electrical circuit (Fig. 6.5). Because the surface area of the pad is so much larger than the active accessory, the current density is very low at the pad site. Proper pad placement is important to evenly disperse the energy and avoid any increase in skin temperature under the pad.<sup>24</sup> Most modern ESUs have dispersive electrode safety alarms available when used in conjunction with "split" or "dual" pads. Patented in 1983, this technology advance is inexpensive and highly recommended, as it markedly reduces the risk of a patient skin burn under the pad.

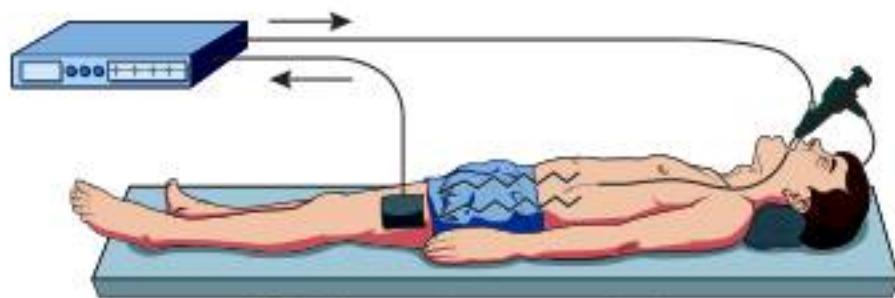

FIG 6.5 A monopolar accessory circuit.

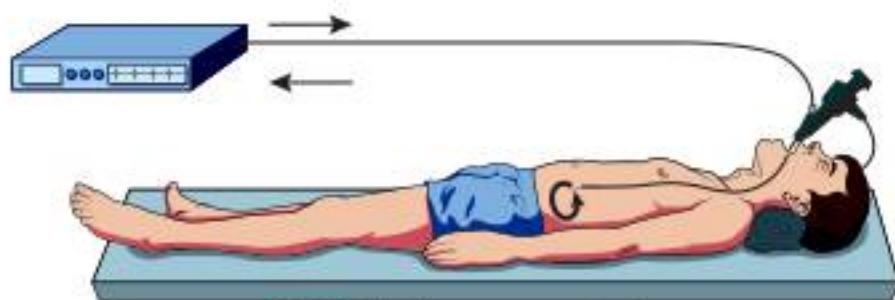

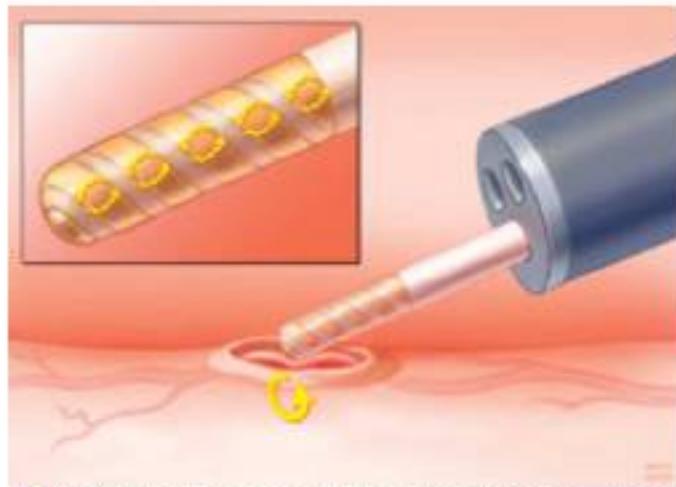

FIG 6.6 A bipolar accessory circuit.

**FIG 6.7** A bipolar hemostasis probe. (From Morris ML, Tucker RD, Baron TH, Song LM: Electrosurgery in gastrointestinal endoscopy: principles to practice. *Am J Gastroenterol* 104(6): 1563–1574, 2009.)

Bipolar (multipolar) accessories are different from monopolar electrodes in that both active and return functions are included in the tip of the instrument. Current flows through a relatively small area of tissue, and there is no need for a dispersive electrode on the patient's skin (Fig. 6.6). The most common flexible endoscopic use for this technology is for contact coagulation using a flexible bipolar hemostasis probe that is supplied by many manufacturers (Fig. 6.7). Bipolar hemostasis probes have been shown to be effective devices for hemostasis for bleeding peptic ulcers, arteriovenous malformations, and other hemorrhagic lesions. Optimal results are obtained by using moderate to firm tamponade in the case of active bleeding. Power settings of 15 to 25 watts are most common. These probes are best used

with generator outputs that have continuous low-voltage outputs paired with a narrow power curve in which the microprocessor control design allows the energy to ramp up quickly in the low-resistance case of frank blood, but to limit the power delivery automatically as the tissue becomes coagulated. Flexible endoscopic bipolar snares, biopsy forceps, and sphincterotomes have also been developed but have not been successfully or widely adopted.

### Radio Frequency Ablation Devices

A newer, important use of bipolar current for thermal therapy is radiofrequency ablation employed to ablate Barrett's esophagus. In this situation, the current moves from one adjacent electrode on a balloon catheter to another. This energy passes via the mucosa and is sufficient to ablate the mucosa, while being superficial enough (< 1 mm depth of ablation) to prevent significant submucosal damage, and minimizing stricture formation.

### Contact and Noncontact Applications

High-frequency electrosurgical energy can be applied to the tissue in either of two ways. The first and far most common method in flexible endoscopy is to have the accessory in direct contact with the surface of the tissue. A well-recognized list of common flexible endoscopic therapies and accessories employ this method: polypectomy and EMR/snares; sphincterotomy/sphincterotomes and needle-knives; contact coagulation/bipolar endostasis probes; coagraspers; and contact coagulators.

In the second way, by using especially high-voltage waveforms with or without the addition of argon (or other) gas to the treatment field, the energy can travel to the tissue surface without the accessory being in contact with the surface.

### Argon-Assisted Coagulation

Argon-assisted coagulation and ablation (also called argon plasma coagulation [APC], argon beam coagulation [ABC], or simply argon coagulation [ArC]) is by far the more prominent noncontact

technique in flexible endoscopy. It has many useful applications<sup>25</sup> including tumor debulking, ablation of vascular malformations,<sup>26</sup> and other hemostasis and ablation therapies.<sup>27</sup> Argon coagulation also has a role in "tidying up" residual adenoma after piecemeal polypectomy or EMR, although overuse in this setting may suggest suboptimal prior resection technique.<sup>28</sup>

In argon-assisted coagulation, argon gas flows from a special catheter tip and becomes electrically charged (ionized) by high voltage, which is concurrently delivered to an electrode in the catheter tip by a specially equipped ESU. The resulting conductive gas plasma arc provides a medium for current flow from the catheter tip to an adjacent mucosal surface. This is a monopolar application and requires the use of a dispersive pad to complete the electrical circuit. It can be used effectively by positioning the catheter tip either in a tangential or perpendicular direction to the mucosal surface. Tangential or perpendicular applications are possible because the arc will always follow the current direction to the nearest tissue without regard to the probe tip design. Although this is a noncontact method, the arc length (and therefore the distance from the tissue surface) achieved is important and variable.

This method can be controlled to promote a very superficial pliant eschar or provide deeper effects and tumor debulking by using longer activations often at higher powers.<sup>29</sup> Although accepted as a generally safe tool, it has been shown that argon coagulation can cause transmural injury at high power outputs,<sup>30</sup> and there have been reports of perforation using this device.<sup>31</sup> In addition, pulsed argon modes have been shown to produce a high rate of pain and patient neuromuscular responses.<sup>32</sup> Nonetheless, the relative ease of use, noncontact speed, ability to arc around folds, and relatively shallow depth of injury make argon coagulation a versatile and indispensable therapy.

The character of the argon beam varies with the several types of systems being marketed. In general, various manufacturers offer standard, amplified, or linear beams. Amplified beams have been termed *high power* due to their higher intensity and correspondingly greater thermal injury. These require that power settings be set lower than either standard or linear beams to compensate.<sup>33,34</sup>

The nature of the high-voltage waveform used to ionize the argon imparts different characteristics to each beam design. It is therefore very important not to assume that power settings or application times will be constant as a user moves from one device to another. It is important to learn and understand the power and time settings suggested by individual manufacturers. Please note that often time of application, either by a first pass of energy or repeated passes, can greatly affect the depth of thermal injury. It is possible to achieve only a few cell layers deep superficial effect or a deeper mucosal injury by varying only the time of application. See Box 6.1: Argon Clinical Pearls to aid in successful outcomes. These usage tips are appropriate no matter which ESU/argon system is in use.

It is possible to induce electrosurgical current to arc in a noncontact fashion without the aid of argon gas. To ionize mixed air in the gap between the accessory and tissue requires high voltages. (Argon gas forms a more stable plasma even in the lower range of these voltages, which is one reason argon is chosen.) The waveforms used to ionize mixed air have crest factors of at least seven or eight and may be named either *spray coag* or *fulgurate*. The ionization of mixed air is less consistent and tends to produce a variable, often charlike and less pliable eschar than when argon gas is present. Smoke may also be produced. These

### BOX 6.1 Clinical Pearls for Best Argon Use with Any System

- Physicians should be sure to use power settings recommended for the system in use—they are NOT all the same!
- Purging the connector and argon probe with nonionized argon at least once before inserting into the endoscope is universally recommended. All systems are equipped with buttons for the automatic activation of this function.
- In addition to the initial purge, it may also be helpful to add another short purge after the probe has been inserted into the scope and is nearing the target site (be sure the tip of the probe is not touching any tissue). This helps bring the gas fully over the ignition electrode which is located at the end of the probe and makes sure an adequate non-ionized argon cloud is surrounding the target site.
- Sometimes approaching the tissue with the probe in a tangential position will help get close to the target treatment site without touching.
- It is OK to gently "lay down" the probe tip and then pull back without delivering energy to gauge distance from the tissue.
- Don't extend the probe too far out of the scope; working closely gives better control. Be sure you see the tip of the probe extending beyond the tip of the endoscope.
- Keep your foot on the energy delivery pedal long enough to get ignition started.
- There are three popular application techniques: "spot welding," "painting," and "ignite and drag." Each has different uses and slightly different techniques. It helps to practice on ex vivo or animal models.
- For the painting technique, move the scope not the probe.
- Increasing the time increases the penetration depth.
- Putting the dispersive (grounding pad) on the flank can shorten the impedance path and help make the beam longer.
- Don't turn up the gas flow trying to make the beam longer. This will only dilute the ions already activated.
- 1 liter per minute flow rate is sufficient for most applications. Increasing the gas flow will lead to more distension of the patient's gut.
- Monitor the patient for distension during the procedure, and use suction frequently, especially for lengthy or pediatric applications. Recall that argon gas is flowing when the foot pedal is depressed even if the beam has not ignited.
- It is not true that having a side or circumferential tip on the argon probe will make it safe to touch the tissue.
- Do not use argon coagulation to treat varices, hemorrhoids, or other lesions requiring tamponade or coaption.

drawbacks, along with historic concerns about capacitive coupling when high voltages are used with endoscopes, have made the use of these nonargon-assisted methods rare in flexible endoscopy, although the method is fairly common in open surgery.

Recently, however, the use of spray coag/fulgurate waveforms have been introduced by some Japanese physicians as an optional output choice for the dissection stage of ESD and peroral endoscopic myotomy (POEM) procedures. No studies of tissue effect and safety of this waveform in these settings are known to have been published to date.

### Electrical Hazards

Being mindful of the monopolar circuit can help prevent some of the most common types of electrosurgical injuries. Once a monopolar snare, for example, is attached to an active cord inserted into the generator socket and the generator is on, it is a potential "active electrode." If the dispersive pad has also been placed on the patient, it is imperative not to place that active electrode (snare) on the bed next to the patient while turning your attention elsewhere. If someone were to activate the foot-switch, the patient could be burned wherever they were in contact

with the snare lying on the bed. The best-practice rule is to carefully manage all active electrodes. Disconnect the accessory from the active cord, or place the generator in "standby" mode, if available, until everyone is actually ready for the electrosurgical procedure. Carefully managing active cords and accessories can also prevent shocks and burns to staff. Handle active electrodes by their plastic insulated areas only, and never attempt to connect or disconnect accessories while current is flowing.<sup>35,36</sup>

Although a published report of an electrosurgical pad burn during a flexible endoscopic procedure is unknown, it is still wise to take advantage of the inexpensive, well-studied safety advantages of using split/dual/sensing dispersive pads. When using any of the many generators that include pad safety and tissue sensing technology in their design, these pads are able to communicate with the generator's computer and alarm system and produce both a visual and audible warning to the operator that the pad is sensing an unbalanced impedance situation that, if not corrected, could result in a temperature rise on the patient's skin under the pad and might increase the risk of a burn. Support staff should be well trained in best practices for the placement of dispersive electrodes.

### Electrosurgery With Implanted Devices

Implanted cardiac pacemakers and cardioverter defibrillators (ICDs) are designed to sense and react to electric signals from the heart. This makes them vulnerable to interference from electrical signals that are not cardiac in origin, and it has long been known that extra care must be taken when using electrosurgery for treating these patients. Patients with these implanted devices can safely undergo electrosurgery as long as certain precautions are taken.<sup>37,38</sup> Newer pacemakers have been engineered to be resistant to electric interference, and alteration in function from electrosurgery is extremely rare in gastroenterology. However, the risk exists, and if interference with the implanted device occurs, the effects could be highly variable and dependent not only on the source and character of the interfering signal, but on the design of the device itself.

Pacemakers can be temporarily inhibited from outputting a signal, or the interference might be interpreted by the device as noise, which can cause the device to revert to an asynchronous pacing mode (a mode in which the device paces but does not sense) at a rate preset by the manufacturer. The interference might be interpreted by the device as a programming signal leading to inappropriate programming of the device. Sometimes the battery life might be affected, or, in the case of ICDs, they may trigger an inappropriate therapy shock to the patient. Most ventricular assist devices have sensitive components contained in external controllers and are not usually affected by electrosurgery, but checking the manufacturer's recommendation is advisable for these devices as well.<sup>34</sup>

Current recommendations for the management of patients with these cardiac devices are based on consensus statements published by individual societies such as the American College of Cardiology Foundation/American Heart Association (ACCF/AHA), the Heart Rhythm Society/American Society of Anesthesiologists (HRS/ASA), and the American Society of Gastrointestinal Endoscopy (ASGE). Whereas agreement between societies is not completely consistent, there is universal agreement that it is recommended that each endoscopy practice have a protocol in place that will be followed when a patient with an implanted device is scheduled. These protocols should be initiated and reviewed by qualified personnel trained in the operation of implanted

cardiac devices. All societies agree that it is imperative to identify the approximately 20% of cardiac pacemaker implant patients who are dependent on their pacemakers for moment-to-moment maintenance of adequate rhythm and hemodynamics.

### Bowel Explosion Risk

It is possible to ignite a fire in the colon in the presence of naturally occurring gases such as hydrogen and methane in the presence of oxygen. Thorough colon preparation using approved preparation techniques with solutions that do not contain mannitol or sorbitol is necessary even if the electrosurgery, including argon coagulation, is used only in the sigmoid colon or rectum.<sup>39,40</sup> Explosion has been reported with the use of ArC in the rectum after enema preparation.<sup>41,42</sup> If electrosurgery must be performed on an unprepared colon, efforts to exchange the gas in the colon with repeated insufflation and suction should be undertaken. Carbon dioxide (CO<sub>2</sub>) insufflation, mainly used for patient comfort, may reduce the risk of gas ignition further.

### Fundamentals in Practice

The following are a summary of key principles of ESU use in flexible endoscopy:

- The final tissue effect seen is the result of both non-ESU and ESU variables
- The ESU variables are the power selection, the waveform selection, and the power curve built into the generator for that waveform selection.
- Non-ESU variables that include the accessory chosen, the time of application, operator technique, and the tissue character can have a defining impact on the final result.
- Current density is the arbiter of the tissue effect. For example, sphincterotomy progresses much better when a small amount of wire is in contact with the tissue. Smaller amounts of tissue have higher current density when everything else is equal.
- Polypectomy cutting may be difficult to initiate if the polyp has a very thick stalk and a large circumference of tissue is in contact with the snare, or if the snare is squeezed too tightly so that more of it is surrounded by tissue. These factors lower the current density. The lower current density tends to slow the heating, producing a greater proportion of coagulation to cutting. A "loosely-snug-and-smooth" snare closing technique is recommended to promote smooth polypectomies.
- Thin accessories focus the energy and raise the current density, thus promoting cutting, whereas broader accessories spread the energy over a wider area and lower the current density, which promotes more coagulation effect.

### Biliary and Pancreatic Sphincterotomy

Transpapillary division of the biliary sphincter has become a routine part of endoscopic retrograde cholangiopancreatography (ERCP) to facilitate biliary access, remove calculi, improve drainage in biliary dyskinesia, prevent biliary stenosis after ampullectomy, and aid in stent placement. Sphincterotomies are done using monopolar current. Most sphincterotomies are performed using a "pull" type of sphincterotome. The tip of the instrument has an exposed wire (20 to 30 mm) that forms a bow with the catheter when a handle is tightened; this puts tension between the cutting wire and the roof of the papilla. Only the tip of the exposed wire is used for cutting (to increase current density and improve operator control of the incision). Most procedures are wire guided with a shielded guidewire in the bile duct to ensure that the pancreatic duct is not inadvertently

incised. Cutting may be performed with either pure cut (100% duty cycle with peak voltage > 200 V; see Table 6.2) or blended (37% to 70% duty cycle; see Table 6.2) current. The use of a cut current results in a more rapid incision with less edema of surrounding tissues, but less hemostasis. Elta<sup>43</sup> et al (1998) first demonstrated that the use of a cut current in lieu of a blended coag waveform (25% duty cycle) resulted in a lower rate of pancreatitis.

As would be expected with less coagulation, increased mild hemorrhage is seen, but this does not translate into clinically significant bleeding.<sup>44</sup> However, because of the potential for less control of a rapid incision with a nonfractionated cut current, great care must be taken with this current output. As mentioned earlier, most new generators have waveform selections that automatically fractionate or interrupt (pulse) the cut current during the course of the incision. As with colonic polypectomy, excessive tissue desiccation should be avoided because this may lead to stalling of the incision.

#### Needle-Knife Sphincterotomy

Needle-knife sphincterotomy employs a fine, stiff wire projecting approximately 5 mm beyond the tip of a catheter. This type of sphincterotomy is used to cut a pathway into the bile duct and is usually reserved for cases of failed cannulation in which biliary access is of particular importance.

#### Complications of Sphincterotomy—Link With Electrosurgery

Common complications of endoscopic sphincterotomy include pancreatitis, hemorrhage, and perforation. Each complication may be influenced by the type of current used.

**Pancreatitis.** Acute pancreatitis is the most common complication of endoscopic sphincterotomy, occurring in at least 5% of cases.<sup>45,46</sup> Development of pancreatitis may be partly a function of iatrogenic trauma to the periampullary region (this trauma results in edema and obstruction to pancreatic flow) or to patient factors such as the presence of Sphincter of Oddi dysfunction. Most current research indicates that generator waveform choice has little effect on post-ERCP pancreatitis as long as a coagulation or blended coagulation waveform with a 25% duty cycle or lower is avoided (see Table 6.2).<sup>45</sup>

**Hemorrhage.** Hemorrhage during endoscopic sphincterotomy is due in part to inadequate coagulation effect of tissue during the incision. Mild oozing at the sphincterotomy site at the time of endoscopic sphincterotomy is common, settles spontaneously, and is of no clinical significance. Minor bleeding at the time of sphincterotomy may be more common with pure cut technique. Significant hemorrhage occurs in 1% to 3% of patients<sup>47</sup> with an associated mortality of less than 1%.<sup>48</sup> This hemorrhage is due to incision of a significant vessel, which is partly "bad luck" and sometimes due to poor orientation of the incision, cutting into a diverticulum or overcutting the incision. Arterial bleeding is not prevented by one electrosurgical output versus another. It is believed, however, that a half-incised vessel (the ends of which cannot retract) bleeds much more than a fully cut one, implying that cutting a little more may be useful in this situation.

**Perforation.** Duodenal perforation during endoscopic sphincterotomy is usually the result of a poorly aligned or too-long incision beyond the boundaries of the intramural common bile duct. Clinically significant perforation occurs in less than 1% of sphincterotomies.<sup>49,50</sup> The risk of perforation may be 8% in patients with a small papilla and patients with papillary stenosis.<sup>51</sup>

Asymptomatic perforation may be more common, possibly occurring in 15% of sphincterotomies.<sup>52</sup> Duodenal perforation may occur during a rapid, uncontrolled cut of the sphincter (*zipper cut*). The occurrence of this type of rapid incision is a function of current delivery to the tissue and operator experience. The use of a pulsed or interrupted advance type of waveform has been shown to reduce this risk.<sup>53</sup>

#### Polypectomy

Polypectomy is most commonly used to remove colonic polyps, either in one piece or piecemeal. Polypectomy and other thermal ablative techniques such as hot biopsy and ablation have the potential to cause transmural damage, resulting in either serosal inflammation (post-polypectomy syndrome) or perforation. The risk of perforation with all colonoscopies has been estimated to be one perforation in a range between 1000 to 2000 colonoscopies.<sup>54</sup> Serositis without perforation occurs in 1% of polypectomies<sup>55</sup> and manifests 6 hours to 5 days after the procedure with pain, fever, and leukocytosis. The right side of the colon is particularly at risk because of its thinner wall.

Immediate hemorrhage occurs in approximately 1% of polypectomies, and delayed bleeding may occur in 2% of polypectomies.<sup>56</sup> Significant hemorrhage is much more likely when cutting through a thick stalk. Delayed bleeding may occur anytime up to 2 weeks after the procedure. From the preceding discussion, it can be seen that sphincterotomy and polypectomy complications may be related partly to either an overrapid, poorly controlled incision or an overdesiccated, poorly progressed incision.

Modern generators use microprocessor-controlled feedback to help produce predictable tissue results in spite of changes in tissue resistance. However, there are patient factors and operator technique that cannot be accounted for by the generator's algorithm (see Fig. 6.1). Bleeding risk, for example, is greatly influenced by patient factors such as anticoagulant use. Dobrowolski et al (2006)<sup>57</sup> reported variance in bleeding rates with polyp size, morphology, and malignant state, whereas Watabe et al (2006)<sup>58</sup> also noted that hypertension puts patients at risk for a delayed post-polypectomy hemorrhage. It is at this intersection of electrosurgery fundamentals and the characteristics of the particular patient presenting for treatment that the physician well schooled in both will consistently experience the best outcomes.

#### Hot Biopsy Forceps

HBF have been a popular means of removing diminutive polyps for many years.<sup>59</sup> HBF employs monopolar circuitry. Blended or coagulation current should be used at a relatively low setting and applied only until blanching of the tissue occurs (1 to 2 seconds). The bowel should be deflated before power application, and care must be taken not to touch other parts of the bowel wall with the cups while coagulating. Post-polypectomy syndrome, perforation, and significant bleeding have all been reported after removal of diminutive polyps using HBF.<sup>19,58</sup> This technique is also relatively poor at removing all polyp tissue.<sup>60</sup>

#### Endoscopic Mucosal Resection

EMR is a method of removing sessile or flat neoplasms involving the mucosal layer of the GI tract. Several methods of EMR exist including injection, cap, and ligation-assisted techniques.<sup>61</sup> All forms of EMR utilize snares to perform the resection. The resection is typically performed using either some form of a

blended-cut current (crest factors of approximately 2.5 to 5.5 [see Table 6.2]) or a coagulation mode similar to that used to perform polypectomy (i.e., broad power curve with a crest factor of approximately 6 [see Table 6.2]). Potential complications associated with EMR include hemorrhage (immediate and delayed) and perforation/full thickness resection.

### Endoscopic Submucosal Dissection

ESD is a method for resecting neoplastic lesions en bloc. In performing ESD, the perimeter of the margin is typically marked using a needle-knife or snare tip using a low-voltage contact coagulation current (100% duty cycle, < 200 V; see Table 6.2). The submucosa is then injected with a solution (typically saline-based) followed by incision of the mucosa around the perimeter of the initial markings. The incision is made using an electrosurgical knife with an ESU setting that delivers a blended current capable of both cutting and coagulation. Following the mucosal incision of the perimeter of the lesion, dissection of the submucosa can be performed with various electrosurgical knives (discussed in detail in Chapters 32 and 37). Various ESU settings will allow the endoscopist to perform the dissection. In selecting the appropriate ESU setting for performing the dissection, factors such as the vascularity and extent of fibrosis need to be considered and often need to be modified during the procedure depending on what is encountered during the resection. If a large vessel or active bleeding is encountered during the resection, the vessel should be coagulated using coagulation graspers with a soft coagulation current (100% duty cycle, < 200 V; see Table 6.2). As previously mentioned in this chapter, the specific ESU settings used for the various aspects of ESD depend on the technique used by the endoscopist, with the tissue effect being largely impacted by the technique and accessory used (see Fig. 6.11). Therefore, a physician performing ESD should have a thorough understanding of electrosurgical principles and the specific operating characteristics of their ESU.

### Peroral Endoscopic Myotomy

POEM is a method to treat achalasia and other esophageal motility disorders by performing a myotomy endoscopically.<sup>51</sup> The procedure and indications are discussed in detail in Chapters 19 and 45. In regard to electrosurgical principles for performing POEM, the procedure utilizes similar devices and techniques to ESD. A submucosal injection is performed proximal to where the myotomy is performed. This is followed by a longitudinal mucosal incision (approximately 2 cm in length) using an electrosurgical knife with ESU setting similar to that for performing the mucosal incision in ESD. The submucosal space is then entered through the mucosal incision. A submucosal tunnel is then created by performing a series of injections into the submucosal space followed by dissection of the submucosa. Various electrosurgical knives and ESU settings can be used for performing the dissection of the submucosal space. The use of "spray coag" (high voltage, high crest factor, short duty cycle current; see Table 6.2) has been reported to be used successfully for dissecting the submucosal space.<sup>52</sup> However, other ESU settings (e.g., blended cut currents or coagulation current with a crest factor of approximately 6; see Table 6.2) can also be utilized to perform the submucosal dissection. Following the creation of the submucosal tunnel past the gastroesophageal junction, the myotomy is then performed using an electrosurgical knife. Again, the choice of ESU setting is dependent on the accessory used, tissue factors, and the operator technique. The setting should

produce a cutting effect along with coagulation. Large vessels and active bleeding can be managed using coagulation graspers using a continuous coagulation current less than 200 V (see Table 6.2).

### SUMMARY

There are a variety of indications for electrosurgery throughout the gastrointestinal tract for cutting or ablating tissue. All these techniques involve manageable risks of perforation or hemorrhage. New accessory devices, techniques, and generators intended to reduce these risks do not replace the responsibility of the clinician to have a working knowledge of the principles underlying the tools in use.

## INTRODUCTION

Sedation is regularly used to facilitate the performance of endoscopic procedures. Sedation practices have noticeably changed over the past decade, with a shift from no or moderate sedation to monitored anesthesia care (MAC) for gastrointestinal (GI) endoscopy.<sup>1</sup>

Sedation during an endoscopic procedure helps in two ways; first, by decreasing procedural pain, thereby making the patient more comfortable, and second, by decreasing any untimely patient movements, thereby reducing complications.<sup>2</sup> Both these factors affect the overall quality and safety of endoscopic procedures.

Sedation is associated with its own potential problems. Sedation-related complications, such as aspiration, oversedation, hypoventilation, and airway obstruction, make up more than half of all reported endoscopic complications.<sup>3,4</sup>

Sedation use requires additional monitoring and recovery, and therefore has implications in the form of time, cost, and staffing. Due to these issues, some prior studies have advocated for the use of unsedated endoscopy<sup>5-7</sup>; however, the rate of use of unsedated endoscopy remains very low in the United States.<sup>8</sup> The main reason for that is unpredictable patient tolerability during the endoscopic procedures. Several studies have shown that even though patients agree to undergo the procedure without sedation initially, the need for sedation later in the procedure causes significant delays in procedure completion

when compared to patients who are sedated throughout the procedure.<sup>9,10</sup>

The length and complexity of procedures and the comorbidities of the patient are the most important factors for sedation use. These factors may influence the choice of sedative, the level of sedation, and the need for an anesthesiologist during the procedure. Patients also vary in their sensitivity to sedation and their tolerance of endoscopy. The American Society of Anesthesiologists (ASA) defines the level of sedation on a spectrum of four recognizable levels, from minimal sedation to general anesthesia<sup>11</sup> (Table 7.1). The most commonly used level in endoscopic procedures is moderate sedation, wherein the patient demonstrates purposeful response to visual or tactile stimuli. This level of sedation can be achieved with a benzodiazepine alone or combined with an opiate. Due to the increased use of MAC, propofol use to target balanced propofol sedation (concurrent use with midazolam and/or fentanyl) is being increasingly used for mild to moderate sedation and is associated with improved patient outcomes.<sup>12,13</sup>

This chapter focuses on all aspects of sedation and patient safety. Patient evaluation and risk assessment, presedation preparation, patient monitoring during sedation, sedation providers, sedation in high-risk populations, and issues of consent are discussed. The attributes of commonly used sedative drugs are discussed in the context of level of sedation and monitoring required.

**Abstract**

Sedation practices have noticeably changed over the past decade as the utilization of esophagogastroduodenoscopy and colonoscopy has steadily risen. Over time, we have seen a dramatic shift from no or moderate sedation to monitored anesthesia care (MAC) for gastrointestinal endoscopy. This shift has led anesthesiologists into the endoscopy suite with newer sedative medications and increased safety concerns. The consequence of this change in sedation practices requires an endoscopist to have a strong foundation regarding many sedation-related issues, including depth of sedation, appropriate patient selection, choice of sedative medications, methods of sedation delivery, patient monitoring, recovery from sedation, and patient outcomes. With the changing landscape of the health care system, the challenges of quality and cost warrant us to provide the best possible care for our patients in the most efficient manner possible. The endoscopy suite is a unique sedation environment, and the purpose of this chapter is to review all aspects pertaining to current sedation practices in gastrointestinal endoscopy.

anesthesiology

**TABLE 7.1 Levels of Sedation**

Level 1: Minimal sedation	Drug-induced state, during which patient responds normally to verbal commands. Cognitive function and coordination may be impaired. Ventilatory and cardiovascular function are unaffected.
Level 2: Conscious sedation	Drug-induced depression of consciousness, during which patient responds purposefully to verbal commands, either alone or accompanied by light tactile stimulation. Patent airway is maintained without help. Spontaneous ventilation is adequate, and cardiovascular function is usually maintained.
Level 3: Deep sedation	Drug-induced depression of consciousness, during which patient cannot be easily aroused but responds purposefully to repeated or painful stimulation. Patient may require assistance maintaining an airway. Spontaneous ventilation may be inadequate, and cardiovascular function is maintained.
Level 4: General anesthesia	Patient is not able to be aroused even by painful stimuli. Patient often requires assistance in maintaining patent airway. Positive-pressure ventilation may be required owing to respiratory depression or neuromuscular blockade. Cardiovascular function may be impaired.

From Bryson HM, Fulton BR, Faulds D: Propofol: an update of its use in anesthesia and conscious sedation. *Drugs* 50(3):513-559; 1996.

**TABLE 7.2 Definition of American Society of Anesthesiologists Status**

Class 1	Patient has no organic, physiologic, biochemical, or psychiatric disturbance. Pathologic process for which operation is to be performed is localized and does not entail systemic disturbance.
Class 2	Mild to moderate systemic disturbance caused either by the condition to be treated surgically or by other pathophysiologic processes.
Class 3	Severe systemic disturbance or disease from whatever cause; it may be impossible to define degree of disability with certainty.
Class 4	Severe systemic disorders that are already life-threatening, not always correctable by operation.
Class 5	Moribund patient who has little chance of survival but is submitted to operation in desperation.

administration of sedative agents. Standard monitoring procedures include electrocardiography, pulse oximetry, blood pressure measurement, and capnography. Monitoring should be discontinued only when the patient is fully awake. According to the ASA guidelines, it is recommended that continuous recording of the patient's level of consciousness, respiratory function, and hemodynamics reduces the risk of sedation-related adverse outcomes.<sup>11</sup> Close monitoring helps in early detection of adverse events induced by sedatives, such as apnea, hypoxemia, hypotension, and arrhythmias, which allows for early intervention to prevent any life-threatening complications. Each of the monitored parameters is addressed in the following sections.

### Level of Consciousness

Alteration in the level of consciousness while under sedation serves as a guide to the depth of sedation the patients. With a decrease in level of consciousness being associated with a loss of reflexes that normally protect the airway and prevent hypoventilation, it is important to assess patient response to commands during sedation (see Table 7.1). Verbal responses also provide information indicating that the patient is breathing. In procedures where verbal responses are impossible, such as upper GI endoscopy, nonverbal responses such as hand movements, finger squeezing, toe wiggling, etc., should be sought. A lack of response to verbal or tactile stimuli suggests a higher depth of sedation and should be managed accordingly.

### Pulse Oximetry

A common noninvasive method of measuring oxygen saturation is pulse oximetry, which uses a light signal transmitted through tissue and takes into account the pulsatile volume changes that occur. The pulse oximeter measures the pulsatile signals across perfused tissue at two distinct wavelengths: the infrared band, which corresponds to oxyhemoglobin, and the red band, which corresponds to reduced hemoglobin.

However, the sole use of pulse oximetry is inadequate for detecting alveolar hypoventilation in patients undergoing endoscopy.<sup>12</sup> This is demonstrated by the oxyhemoglobin dissociation curve. A high oxyhemoglobin concentration is preserved despite a decrease in partial pressure of oxygen in the blood ( $\text{PaO}_2$ ) until the  $\text{PaO}_2$  falls below 60 mm Hg, at which point the pulse oximeter reading reflects the decreasing  $\text{PaO}_2$  with a rapid

### PROCEDURAL MONITORING

Patients should have continuous monitoring while undergoing endoscopic procedures and also before, during, and after the

decrease in oxygen saturation. Therefore, alveolar hypoventilation is detected earlier with the use of capnography (described later) than pulse oximetry.<sup>10</sup>

### Pulmonary Ventilation

Respiratory depression in the form of transient hypoxemia is not uncommon with sedation use and is usually trivial. It is also encountered in unsedated procedures. Extended periods of hypoxemia, however, can cause tachycardia and coronary ischemia. Therefore, respiratory monitoring is very important to reduce the risk of adverse outcomes.

Direct observation of respiratory movement or direct pulmonary auscultation is the simplest way to monitor ventilator function. A noninvasive method for measuring arterial carbon dioxide is transcutaneous carbon dioxide monitoring ( $\text{PtCO}_2$ ), which entails placing a heated electrode on the skin, causing the microcirculation to "arterialize." The eventual production of carbonic acid due to diffusion of carbon dioxide into an electrolyte solution provides a pH reading by using the Henderson-Hasselbalch equation, which allows for calculation of the arterial carbon dioxide level. The use of this technique was validated by Nelson et al (2000), who demonstrated significantly more  $\text{CO}_2$  retention in patients with standard monitoring than those with standard monitoring coupled with  $\text{PtCO}_2$  monitoring in patients undergoing endoscopic retrograde cholangiopancreatography (ERCP).<sup>11</sup>

Capnography is the gold standard for respiratory monitoring. It works by measuring the  $\text{CO}_2$  indirectly by virtue of light absorption in the infrared region of the electromagnetic spectrum.  $\text{CO}_2$  retention is identified as an early event on capnography and is a sign of ventilation compromise. It serves as a qualitative method for detection of  $\text{CO}_2$  levels in nonintubated patients undergoing endoscopy, as the exact measurement of  $\text{CO}_2$  is inaccurate unless the breathing system is a closed circuit, such as in intubated patients. There have been several studies that have demonstrated that use of capnography detects significantly more hypoxemia in patients undergoing GI endoscopy than standard monitoring.<sup>12,13</sup> However, a 2016 trial did not demonstrate any reduction in the incidence of hypoxemia events in healthy individuals undergoing routine endoscopy targeting moderate sedation.<sup>14</sup>

Bispectral index (BIS) monitors are often used in the operating room to assess the adequacy of the depth of anesthesia while under a general anesthetic in patients undergoing surgical procedures. However, the BIS monitor has significant overlap of scores across sedation levels when it is used to detect deep sedation, resulting in an overall lower accuracy rate.<sup>20</sup>

### Hemodynamic Measurements

Hemodynamic complications, such as hypotension, arrhythmias, and cardiovascular response to stress, are some of the mild direct effects of sedative agents and analgesics that may happen during sedation. Regular measurements of pulse and blood pressure can help detect these changes, which may represent responses to hypoxemia, oversedation, or possibly patient distress to procedure-induced pain. Although no evidence shows that blood pressure monitoring during endoscopy influences morbidity and mortality, it has been recommended that both regular blood pressure measurements and pulse be monitored throughout procedures performed under sedation.<sup>1</sup> Continuous electrocardiogram (ECG) monitoring should be considered in high-risk patients, such as patients with known disturbances in

cardiac rhythm, cardiomyopathies, or ischemic heart disease. The requirement for ECG monitoring has not been evaluated in clinical trials.

### Supplemental Oxygen

Supplemental oxygen administered via nasal cannulas or a mask has been shown to reduce the incidence of desaturation during endoscopy performed under sedation<sup>21,22</sup> and hence it should be given to all patients receiving sedation. However, as supplemental oxygen may delay the onset of hypoxemia in sedated patients with decreased pulmonary ventilation, it is essential not to rely solely on pulse oximetry to monitor ventilation but to employ additional techniques, such as capnography or a BIS monitor.

## INTRAVENOUS ACCESS

Intravenous access should be maintained throughout the procedure until the patient is no longer at risk from cardiopulmonary or respiratory depression. It facilitates the immediate availability of vascular access in the event of oversedation for administration of reversal agents or for using emergency drugs in the event of cardiopulmonary compromise. In patients who are receiving sedatives via nonintravascular routes (e.g., pediatric patients undergoing endoscopic procedures), intravenous access should also be obtained if the likelihood of any cardiopulmonary depression is high.

### SEDATION AND CONSENT

There are a couple of important things to keep in mind when it comes to consent and sedation. First and foremost, the patient should be fully informed of the indications, risks, and alternatives to sedation before he or she consents to the procedure. The second important issue is whether a patient, while under sedation, can withdraw consent for the procedure. If a sedated patient indicates during endoscopy that he or she wishes to have the procedure stopped, should the endoscopist stop or complete the procedure, bearing in mind that it would be in the patient's best interests to complete it? A study from the United Kingdom researched this issue and found that 88% of gastroenterologists stated that they would only stop after repeated requests by the sedated patient, and only 45% of gastroenterologists thought patients were capable of making rational decisions while under sedation.<sup>23</sup> When looked at from the patient's perspective, the study found that opinion was evenly divided into terminating the procedure immediately or completing it.<sup>23</sup>

### STAFFING LEVELS AND TRAINING

Adequate patient monitoring during sedation is difficult for a clinician performing the procedure. There should be additional individuals available to monitor the patient's status in terms of level of consciousness, ventilatory function, and hemodynamic parameters. The presence of another individual is likely to improve patient comfort and satisfaction. Several areas of expertise are required while managing sedated patients, including knowledge of administered drugs and management of adverse events. All staff members administering sedative drugs should be made familiar with the pharmacology of all drugs used prior to their involvement. Particularly, staff members should be aware of the basics such as the time to onset of action, elimination half-life,

### **BOX 7.1 Appropriate Emergency Equipment to Have Available When Using Sedative or Analgesic Drugs Capable of Causing Cardiorespiratory Depression**

Appropriate emergency equipment should be available whenever sedative or analgesic drugs capable of causing cardiorespiratory depression are administered. The following lists should be used as a guide, which should be modified depending on the individual practice circumstances. Items in brackets are recommended when infants or children are sedated.

#### **Intravenous Equipment**

- Gloves
- Tourniquets
- Alcohol wipes
- Sterile gauze pads
- Intravenous catheters [24–22-gauge]
- Intravenous tubing [pediatric “microdrip” (60 drops/mL)]
- Intravenous fluid
- Assorted needles for drug aspiration, intramuscular injection [intraosseous bone marrow needle]
- Appropriately sized syringes (1-mL syringes)
- Tape

#### **Basic Airway Management Equipment**

- Source of compressed oxygen tank with regulator or pipeline supply with flowmeter
- Source of suction
- Suction catheters [pediatric suction catheters]
- Yankauer-type suction
- Face masks [infant/child]
- Self-inflating breathing bag-valve set [pediatric]
- Oral and nasal airways [infant/child-sized]
- Lubricant

#### **Advanced Airway Management Equipment (for practitioners with intubation skills)**

- Laryngeal mask airways [pediatric]
- Laryngoscope handles [tested]
- Laryngoscope blades [pediatric]
- Endotracheal tubes
  - Cuffed 6.0, 7.0, 8.0 mm ID
  - Uncuffed 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, 6.0 mm ID
- Stylet (appropriately sized for endotracheal tubes)

#### **Pharmacologic Antagonists**

- Naloxone
- Flumazenil

#### **Emergency Medications**

- Epinephrine
- Ephedrine
- Vasopressin
- Atropine
- Nitroglycerin tablets or spray
- Amiodarone
- Lidocaine
- Glucose, 50% (10% or 25%)
- Diphenhydramine
- Hydrocortisone, methylprednisolone, or dexamethasone
- Diazepam or midazolam

ID, internal diameter.

From American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists: Practice guidelines for sedation and analgesia by non-anesthesiologists. *Anesthesiology* 96(4):1004–1017, 2002.

interactions, adverse reactions, contraindications, and pharmacology of appropriate antagonists.

Individuals monitoring sedated patients should be able to recognize complications associated with the sedative drugs. Since most of the complications associated with sedatives are cardio-pulmonary in nature, at least one individual should be familiar with advanced airway and ventilation management. Guidelines recommend an advanced resuscitation provider be immediately available in the event of an emergency.<sup>11</sup> Resuscitation equipment should be readily available and must include a cardiac defibrillator, advanced airway and positive-pressure ventilation equipment, and all the appropriate drugs, including sedative antagonists (Box 7.1).

## **POSTPROCEDURAL MONITORING**

The patients remain at risk of sedative-related complications even after completion of the procedure. The risk of upper airway obstruction and hypoxemia after significant moderate sedation for ERCP seems to be greatest immediately after removal of the endoscope. Monitoring of the patient should be continued until the patient has reached an acceptable level of consciousness, with normal ventilation, oxygenation, and hemodynamic parameters. Before discharging the patient, it should be recognized that there may be a prolonged period of amnesia with impairment of cognition and judgment, even though the patient's conscious level may appear normal. Patients may also be mildly dehydrated,

especially after colonoscopy, and fluid replacement should be addressed before discharge planning.

After an outpatient procedure, the following instructions should apply for at least 24 hours after discharge:

- Patients should not drive.
  - Patients should not operate heavy or dangerous machinery.
  - Patients should not sign any legally binding documents.
  - Patients should be given written instructions regarding “warning signs and symptoms” of any adverse outcomes of the procedure and contact numbers for 24-hour advice.
- In addition to the previous points, patients should arrange for a ride home beforehand, and that should be confirmed with the patient before starting the procedure.

In a placebo-controlled study, flumazenil use was shown to augment recovery from sedation and amnesia without any apparent risk for re-sedation.<sup>24</sup> Although use of flumazenil adds to the costs of the procedure, it still may be preferable for some patients. Use of flumazenil does not preclude the need for postprocedural monitoring, and there is currently not enough evidence to support its routine use.

## **DRUGS FOR SEDATION**

An ideal sedative agent should have the following characteristics:

- Rapid onset of action
- Practical means of delivery
- Short half-life with rapid recovery

- Safe with predictable sedative response (pharmacodynamics)
  - Minimal or no cardiovascular or respiratory effects
  - Effective in producing a calm, pain-free, cooperative patient
- The most commonly used class of drugs are benzodiazepines, which are used alone or in combination with an opiate. It is vital that clinicians are familiar with a few specific sedatives (e.g., midazolam or fentanyl). Most recently, propofol has become the agent of choice to induce deep sedation. Midazolam and diazepam are also frequently used and have been shown to have similar efficacy when compared to each other.<sup>23,26</sup> Midazolam is an attractive agent for endoscopy owing to its rapid onset of action, short half-life, and amnestic properties.

Fentanyl and meperidine are the most frequently used opiates, with fentanyl being preferred and commonly used because of its rapid action and absence of nausea.

The use of a benzodiazepine and an opiate is the most frequently utilized combination in endoscopic procedures, although this concurrent use may lead to an increased incidence of sedation-related complications.<sup>27</sup> Combination therapy in colonoscopy and upper GI endoscopy, however, does not seem to improve pain and tolerance when compared with individual agents.<sup>27-29</sup>

The safest method of administration is by giving small incremental doses until the desired level of sedation is attained, rather than giving a single bolus dose based on patient weight.

Droperidol used to be used in the sedation of agitated patients; however, due to its numerous side effects, it is not widely utilized anymore. Nitrous oxide has also been infrequently used as a form of patient-controlled analgesia in several studies involving colonoscopy.<sup>30,31</sup> Potential benefits of its use include an absence of sedation-related risks and a rapid recovery. However, studies utilizing nitrous oxide were inconsistent and showed minimal to no benefit compared with traditional sedation.

## PROPOFOL AND DEEP SEDATION

In certain circumstances, standard moderate sedation is not sufficient, and patients may require a higher level of sedation. These circumstances include patients who are not tolerant of endoscopy under moderate sedation and in procedures that are painful, longer, or complex, such as ERCP, endoscopic ultrasound (EUS), balloon enteroscopy, and endoscopic submucosal dissection (ESD). Deep sedation can be achieved with benzodiazepine and narcotic combinations. Fentanyl, remifentanil, and meperidine all have been combined with benzodiazepines and narcotics to accentuate sedative effects to achieve deep sedation.

Propofol is a popular drug that is frequently used for GI endoscopy because of its highly favorable pharmacokinetics. Its short half-life, rapid onset of action, rapid recovery times, and attainable depth of sedation make an attractive agent for endoscopic procedures. It has no analgesic properties. Patients who regularly use sedatives and narcotics are often insensitive to standard benzodiazepine sedation and may benefit from propofol sedation. There are several disadvantages associated with propofol use. Propofol has to be continuously titrated to maintain sedation due to its short half-life. The narrow therapeutic window between moderate sedation, deep sedation, and anesthesia necessitates close monitoring. As a result of peripheral vasodilation and impairment of cardiac contractility, propofol may cause profound hypotension. Propofol causes apnea more readily than midazolam, so managing the airway and pulmonary ventilation is more critical if propofol is used.

## NEWER AGENTS

Remimazolam is the latest drug innovation in anesthesia. It is an ester-based benzodiazepine designed to be used for short-duration sedation. It has an organ independent metabolism and is rapidly hydrolyzed by tissue esterases without producing any active metabolites. The sedation effect is shorter than midazolam, and frequent dosing may be required for procedure completion. Preliminary studies have suggested that the recovery time is similar to midazolam, although remimazolam recovery times lack the long outliers seen with midazolam sedation.<sup>32</sup>

Fospropofol is a prodrug that is enzymatically converted to propofol in the liver with a delayed onset of action (4–8 min) and extended duration of action (20–30 min).<sup>33</sup> It may decrease the need for frequent administration, which is often seen with propofol; however, because it needs to be converted to propofol, it has a decreased clinical effect compared to propofol. Fospropofol failed to gain popularity due to several inaccuracies that were reported in the published fospropofol pharmacokinetic-pharmacodynamic data. This led to the retraction of six studies, and correct data is yet to be made available.<sup>34</sup>

Dexmedetomidine is an  $\alpha_2$ -adrenoreceptor agonist with sedative, anxiolytic, and analgesic effects. Its effects on respiratory system are minimal, and it does not cause clinically significant respiratory depression.<sup>35,36</sup> It can be administered either intranasally or intravenously, although the latter is preferred.<sup>37</sup> Dexmedetomidine is delivered as an initial bolus infusion of 1  $\mu$ g/kg over 10 min followed by continuous infusion of 0.6  $\mu$ g/kg per hr that may be titrated between 0.2 to 1.0  $\mu$ g/kg per hr. Dose modification is often necessary in elderly or critically ill patients. Side effects include bradycardia and a biphasic change in blood pressure (high then low) with administration of increasing concentrations.<sup>38</sup> Dexmedetomidine alone or dexmedetomidine with meperidine and midazolam has shown to have less respiratory depression and higher patient satisfaction scores for routine endoscopy and more advanced procedures (e.g., ERCP) than midazolam alone or midazolam with meperidine.<sup>39,40</sup> Dexmedetomidine causes less respiratory depression even when administered with propofol as compared to propofol administered with sufentanil, meperidine, or midazolam.<sup>41</sup>

## SEDATION PROVIDERS

In the United States, moderate sedation is usually administered by an endoscopist, whereas anesthesiologists are the ones managing sedation for MAC or general anesthesia. There are several alternative methods of sedation for endoscopy, which include patient-controlled sedation (PCS), automated delivery using methods such as the SEDASYS system (Ethicon Endosurgery, Inc., Somerville, NJ), and nonanesthesiologist-administered sedation using centrally acting agents such as propofol.

Nearly all endoscopic procedures in the United States are completed with some form of sedation, whereas nearly three-fourths of all endoscopies performed in Europe and Asia are completed without sedation.<sup>42</sup> The percentage of patients undergoing endoscopic procedures (simple or advanced) with MAC or deep sedation in the United States continues to rise. A national survey in 2006 concluded that roughly 75% of patients undergoing endoscopic procedures in the United States received moderate sedation and 25% received deep sedation. Presently, the regions with the highest anesthesiologist-administered sedation rates are the South and Mid-Atlantic states.<sup>43</sup> Cooper et al

(2013) showed that from 2000 to 2009, anesthesia services were used in 40% of the total endoscopies performed in the northeastern United States.<sup>44</sup>

### SEDASYS

In 2013, the US Food and Drug Administration (FDA) approved the SEDASYS system (Ethicon) for minimal to moderate sedation in ASA class 1–2 patients who are at least 18 years old and have a body mass index (BMI) less than 35 for elective esophagogastroduodenoscopy (EGD) and colonoscopy with a requirement that an anesthesiologist be "immediately available" in case of any complications. It was designed to be used with an initial fentanyl dose, followed by a propofol bolus delivered over 3 to 5 minutes, and then an adaptable propofol infusion. It had shown promise when compared with moderate sedation for endoscopy in low-risk patients, with better recovery times and greater satisfaction with SEDASYS among patients and clinicians.<sup>45</sup> There is no direct comparison between SEDASYS and anesthesiologist-delivered sedation in the current literature. A very limited number of hospitals in the United States adopted SEDASYS. As a result, in May 2016, the manufacturer (Johnson & Johnson, New Brunswick, NJ) decided to remove it from the market due to a lack of popularity.

### Patient-Controlled Sedation (PCS)

PCS uses the same hardware as patient-controlled analgesia with drugs (propofol, opioid, and/or benzodiazepines) chosen by the endoscopist. PCS has been shown to be successful in several small studies of both simple and advanced endoscopic procedures.<sup>46,47</sup> Anesthesiologist-administered propofol and PCS have equal satisfaction for ERCP but with shorter recovery times and less frequent use of minor airway interventions, such as chin lifts, in the PCS group. In one study, anesthesiologist intervention was required to complete ERCP in 7% of PCS cases.<sup>48</sup>

### Gastroenterologist-Directed Propofol Sedation

Worldwide, gastroenterologists favor using propofol as a sedative for endoscopic procedures over traditional sedatives. In Switzerland, gastroenterologists administer propofol in both hospital and private practice settings, reflecting successful implementation of nonanesthesiologist-administered propofol-based sedation in other countries.<sup>49</sup> A 2014 large German study of 24,441 endoscopic procedures with gastroenterologist-directed propofol sedation in ASA class 1–3 patients with BMI less than 40 and without obstructive sleep apnea (OSA) (ASA class 3 patients with cardiac issues were also excluded) concluded that the incidence rate for major adverse events (such as apnea or laryngospasm requiring mask ventilation or intubation) was only 0.016%, with the incidence of minor adverse events being just 0.46%. All affected patients made a full recovery.<sup>50</sup> Anesthesia was titrated between moderate to deep sedation.

The latest guidelines of the European Society of Gastrointestinal Endoscopy for the administration of propofol for GI endoscopy by nonanesthesiologists consist of involving an anesthesiologist in high-risk patients, such as those with an ASA classification of 3 or higher, with a Mallampati score of 3 or higher, with conditions that put them at risk for airway obstruction, chronically receiving significant amounts of narcotics, or for whom a lengthy or a complicated procedure is anticipated.<sup>51</sup>

The FDA regulations on propofol state, "For general anesthesia or MAC sedation, Diprivan Injectable Emulsion (Fresenius Kabi USA LLC, Lake Zurich, IL) should be administered only by

persons trained in the administration of general anesthesia and not involved in the conduct of the surgical/diagnostic procedure."<sup>52</sup> This statement has grossly limited the use of propofol by non-anesthesia providers in the United States.

A fairly large 2017 meta-analysis found no difference in rates of overall complications between endoscopist-directed propofol administration and nonendoscopist-directed propofol administration.<sup>52</sup>

## SEDATION IN DIFFERENT PATIENT POPULATIONS

### Endoscopy in Patients With Cirrhosis

Chronic liver disease is one of the most common indications for emergent endoscopy. Liver dysfunction reduces both the clearance of the drugs eliminated by hepatic metabolism and plasma protein binding. It is also associated with a reduction in drug-metabolizing enzyme activities such as the Cytochrome P450 (CYP450) enzymes. Therefore, in patients with advanced liver disease, it is imperative to adjust the dose of those drugs eliminated by renal excretion.<sup>53</sup>

A 2015 meta-analysis concluded that propofol provided more prompt sedation and recovery from EGD than midazolam in cirrhotic patients, with no difference in incidence of side effects.<sup>54</sup>

### Endoscopy Without Sedation

Unsedated endoscopy is facilitated by use of ultraslim endoscopes (<5.9 mm in diameter). The transnasal route of EGD has a higher patient acceptance rate and is preferred by more patients as compared to conventional EGD with or without sedation.<sup>55</sup> However, the disadvantages of the transnasal EGD are the inferior image and the smaller biopsy samples.<sup>56</sup>

### Endoscopy and Pregnancy

Endoscopic procedures in pregnant patients are rarely required and should only be done for the most convincing indications, such as significant GI bleeding, severe nausea and vomiting, dysphagia, and severe diarrhea (all of which may impact maternal and fetal nutrition), as well as biliary pancreatitis or cholangitis.<sup>57</sup> The procedures should be deferred to the second trimester whenever possible to decrease the impact of anesthesia drugs on fetal development.

Both the mother and fetus are at risk for adverse events with endoscopy and, more significantly, anesthesia. A comprehensive discussion of the risks to the fetus and mother with a preoperative obstetrician consultation should be compulsory during the informed consent process for endoscopy. Monitoring of fetal heart rate may be performed during the endoscopy or before and after the procedure.

The left lateral position is recommended for the procedure to avoid compression of inferior vena cava or aorta and prevent compromise of the fetal circulation. Any exposure to radiation should absolutely be avoided. If an ERCP is required, patient position should be appropriate with a lead apron shielding the uterus. An expert should perform the procedure and preferably use a nonfluoroscopy technique.<sup>58</sup>

Anesthesiology services are recommended to be involved during endoscopic procedures involving pregnant patients. There is an increased risk for aspiration in pregnant patients due to elevated intraabdominal pressure and decreased lower esophageal sphincter tone. Maternal hypoxia and/or hypotension may result in reduced uterine blood flow and affect fetal viability.<sup>59</sup>

To summarize, endoscopic procedure time should be minimized, special attention must be paid to the indication for the procedure and patient positioning, fetal monitoring should be made a priority and, if possible, all procedures should be deferred to at least the second trimester.

### Endoscopy in Obese Patients

Obese patients are at risk for OSA and adverse cardiovascular events during endoscopic procedures.<sup>60</sup> These patients can be stratified into groups at high and low risk for OSA using the STOP-BANG (Snoring, Tiredness, Observed apnea, blood Pressure, Body mass index, Age, Neck circumference, and Gender) screening tool.<sup>61</sup> The STOP-BANG score may help in predicting sedation-related adverse events in obese patients undergoing advanced, but not routine, endoscopic procedures.<sup>61,62</sup>

EGD can be safely performed with moderate sedation in most patients with a Roux-en-Y gastric bypass unless the coexisting medical conditions necessitate anesthesia monitoring.<sup>63</sup> In a comparison with those without a bypass, patients with Roux-en-Y gastric bypass required higher doses of fentanyl and midazolam during EGD. The dose of drugs required for sedation increased after gastric bypass despite the resulting weight loss.<sup>64</sup>

## SEDATION FOR DIFFERENT ENDOSCOPIC PROCEDURES

### Standard Endoscopic Procedures

Propofol has been compared with traditional sedative agents such as midazolam, meperidine, and fentanyl in several trials during standard endoscopic procedures.<sup>65–68</sup>

Propofol was shown to be safer and more effective than traditional sedative agents for maintaining an adequate level of sedation during endoscopy, resulting in better titration of the level of sedation and a shorter recovery time.<sup>69</sup> A 2017 meta-analysis of 27 studies did not find any difference in cardiopulmonary complications between propofol and traditional sedative agents for GI endoscopy.<sup>70</sup>

Balanced propofol sedation targeted to induce moderate sedation in patients undergoing upper GI endoscopy was also shown to result in better patient satisfaction and a shorter recovery time than standard sedation alone.<sup>71</sup>

### Propofol Use in Complex Endoscopic Procedures

The use of propofol in complex and prolonged procedures has also been investigated extensively.<sup>70–72</sup> Patients undergoing ERCP are increasingly using MAC instead of moderate sedation. Most of these procedures are performed today without any need for endotracheal intubation.<sup>73</sup> Studies have evaluated the use of balanced propofol sedation in patients undergoing ERCP, with recovery times being longer than in patients undergoing sedation only with propofol.<sup>74</sup> In addition, deep biliary cannulation rates for moderate and deep sedation have shown to be similar.<sup>75</sup>

In Europe, gastroenterologists have transitioned to using propofol sedation in patients undergoing EUS. Recently, a study from Spain (2012) concluded that nonanesthesiologist-administered propofol-based sedation for upper EUS in high-risk and average-risk patients had a low rate of minor complications and no major complications.<sup>76</sup> General anesthesia use assists in EUS-guided fine-needle aspiration of pancreatic masses by decreasing patient movement and resulting in an increased diagnostic yield.<sup>77</sup>

ESD is an emerging procedure in the United States. Unlike standard endoscopy, ESD is associated with pain throughout the

procedure, such as during the incision and dissection phases, as well as the distension and endoscope movement required to perform the procedure. Therefore, deep sedation is a prerequisite for these patients. MAC without endotracheal intubation in patients undergoing esophageal or gastric ESD reduces body movement and provides a safer treatment environment in these difficult and prolonged cases.<sup>78</sup> A 2015 comparison of two sedation protocols, moderate sedation with analgesic supplementation (MSAS) and analgesia-targeted light sedation (ATLS), showed that ATLS did not affect the ESD performance while producing a lower incidence of desaturation events and decreased incidence of aspiration pneumonia.<sup>79</sup> Propofol-remifentanil infusion regimens were used in this study to achieve the desired level of sedation.<sup>79</sup>

## PHARYNGEAL ANESTHESIA IN SEDATION

Topical anesthetic agents are frequently used to suppress the gag reflex in upper endoscopy in addition to sedation. The most commonly used agents are lidocaine, benzocaine, and tetracaine, administered as an aerosol spray to the pharynx. Pharyngeal anesthesia in conjunction with intravenous or intramuscular sedation during upper endoscopy was shown to improve ease of endoscopy and patient tolerance in a meta-analysis.<sup>80</sup> Topical anesthetics have been associated with severe adverse effects such as aspiration, anaphylaxis, or methemoglobinemia and hence should be used cautiously.

## MANAGEMENT OF OVERSEDATION

Sedative agents have been associated with more than 50% of all endoscopy-related complications, the most common being oversedation, hypotension, and respiratory depression. Studies have shown that the expected mean desaturation during all endoscopic procedures is approximately 3% from baseline during sedation.<sup>81</sup> The availability of reversal agents for sedative drugs (i.e., benzodiazepines and opioids) are associated with a reduced risk of sedation-related adverse events. The specific antagonists that are available are flumazenil for benzodiazepines and naloxone for opioids.

However, no such antagonists exist for propofol and that is the biggest disadvantage of using this drug. Even though its short half-life may lead to a rapid reversal of sedation, cardiopulmonary compromise in the interim may prove to be disastrous in the absence of an anesthesiologist.

In patients who have received both a benzodiazepine and an opioid, flumazenil reverses sedation but not respiratory depression. Similarly, naloxone monotherapy has not been shown to reverse respiratory depression induced by opioid and benzodiazepine combinations. In the setting of combination therapy-induced respiratory depression, it is recommended that naloxone is given in addition to flumazenil. At the time of reversal or before reversal, the following should be done:

- Perform basic airway management
  - Clear airway including suction (if appropriate)
  - Jaw thrust maneuver
  - Guedel airway if necessary
- Administer supplemental oxygen or increased oxygen
- Encourage or stimulate deep breaths
- Administer positive-pressure ventilation if spontaneous ventilation is inadequate

Flumazenil and naloxone were previously reserved only for treatment of oversedation and respiratory depression. However,

the long recovery times experienced with benzodiazepine use have prompted some research into the feasibility of routine use of flumazenil with potential cost savings.<sup>14,52</sup> The cost-effectiveness of this routine use is still under investigation.

## REVIEW OF SPECIFIC DRUGS

### Benzodiazepines

Benzodiazepines are central nervous system (CNS) depressants that induce sedation, hypnosis, amnesia, and anesthesia. The mechanism of action seems to intensify the physiologic inhibitory mechanisms mediated by  $\gamma$ -aminobutyric acid (GABA).

#### Midazolam

**Pharmacology.** Midazolam is a short-acting benzodiazepine with an intravenous peak onset of action of 2 to 5 minutes depending on the dose given and level of consciousness attained. If given with an opioid, the onset of action is more rapid (1.5 minutes), sedation is deeper, and a dose reduction of 30% is recommended. At doses sufficient to induce sedation, midazolam decreases the ventilatory response to increased CO<sub>2</sub> in normal patients and in specific patients with chronic airway limitation. The pharmacokinetic profile of midazolam is linear, over 0.05 to 0.4 mg/kg, lending predictable dosage titration. The elimination half-life is 1 to 2.8 hours with a large volume of distribution. The drug is metabolized rapidly to 1-hydroxymethyl midazolam in the liver, conjugated, and secreted in the urine. The elimination half-life is increased in elderly patients and patients with renal failure.

**Administration.** Midazolam should be titrated in doses of 0.5 to 2 mg at intervals of 2 to 3 minutes to a total dose of 5 mg. Higher doses may be required but should be used with caution.

**Precautions and adverse reactions.** When given with an opioid analgesic, there is an increased sedative effect necessitating administration in small incremental steps and a usual requirement of a 30% reduction in dose. Sensitivity increases with age. Caution is required when using midazolam in elderly patients, patients with hepatic or renal impairment, and patients with airflow limitation. Owing to a reduced rate of plasma clearance, patients with heart failure eliminate midazolam more slowly. Paradoxical reactions may occur with restlessness, agitation, and disinhibition. Hypotension is a recognized association of midazolam, particularly if given with an opioid.

**Contraindications.** Midazolam should not be given to patients with myasthenia gravis, alcohol intoxication, or narrow-angle glaucoma.

**Interactions.** The sedative effects of midazolam are enhanced by other CNS depressants, including neuroleptics, alcohol, tranquilizers, antidepressants, analgesics, antiepileptics, and anxiolytics. The effects of midazolam are attenuated by drugs that induce cytochrome P450 (rifampicin, carbamazepine, and phenytoin) and enhanced by inhibitors (erythromycin, diltiazem, antiviral agents, and fluconazole). In particular, midazolam should be given with care in patients receiving combination antiretroviral therapy.

#### Diazepam

**Pharmacology.** Diazepam is metabolized in the liver to the active metabolites temazepam, nordiazepam, and oxazepam, all of which are renally excreted. Plasma concentrations of diazepam and its active metabolites exhibit considerable interpatient variation. The intravenous plasma time curve is biphasic, with

an initial rapid increase with a half-life of up to 3 hours and a second elimination phase with a half-life of 20 to 70 hours. The elimination half-life is increased in elderly patients and in patients with renal and hepatic impairment.

**Administration.** Diazepam should be titrated in doses of 2 to 4 mg to a total of 10 to 20 mg in some circumstances.

**Precautions and adverse reactions.** Caution is required in patients with renal, hepatic, and cardiopulmonary impairment. Hypotension occurs rarely. Other precautions, contraindications, and drug interactions are similar to midazolam.

### Opioid Analgesics

#### Fentanyl

**Pharmacology.** Fentanyl is a synthetic opioid with an estimated 80-fold greater potency than morphine. In contrast to other opioids, fentanyl does not induce histamine release. After intravenous injection, fentanyl reaches peak analgesic effects within 1 to 2 minutes, with a duration of 30 to 60 minutes. Serum concentrations decrease rapidly within 5 minutes to 20% of peak concentrations, followed by a slow decrease over 30 minutes. The drug is metabolized in the liver to active metabolites, all of which are excreted in the urine.

**Administration.** A dose of 50 to 100 µg should be given before administering a benzodiazepine to enable accurate sedative dose titration.

**Precautions and adverse reactions.** Fentanyl causes respiratory depression for periods extending beyond the analgesic effect. In light of the route of elimination, a reduced dose should be used in hepatic and renal impairment. In view of the marked respiratory depression that can occur with its use, caution is required in patients with pulmonary disease.

**Contraindications.** Fentanyl may cause severe bronchospasm and is contraindicated in patients with asthma. Fentanyl may cause severe muscle rigidity and is contraindicated in patients with myasthenia gravis.

**Interactions.** The sedative effect of fentanyl is enhanced by other CNS depressants, such as other opioids, benzodiazepines, alcohol, neuroleptics, and tranquilizers. In particular, fentanyl has been associated with hypotensive adverse events with monoamine oxidase inhibitors and neuroleptics.

#### Meperidine

**Pharmacology.** Meperidine is a synthetic opioid with sedative and analgesic properties. Similar to other narcotics, meperidine causes respiratory depression and suppresses the cough reflex. The sedative and analgesic effects of meperidine after intravenous dosing occur within 2 to 4 minutes, and the analgesic effects can last 4 hours. The elimination half-life is 3.2 hours, and metabolism is predominantly hepatic conjugation. Meperidine elimination is prolonged in patients with hepatic impairment.

**Precautions and adverse reactions.** Care should be taken when giving meperidine concurrently with other neurodepressants. The most common adverse reaction is respiratory depression. Meperidine may also result in profound hypotension. One active meperidine metabolite, normeperidine, has convulsant properties, and elimination is prolonged in patients with renal impairment and elderly patients. In these patients, high doses of meperidine may lead to convulsions, agitation, irritability, and tremors.

**Administration.** Meperidine should be given at an intravenous dose of 25 to 50 mg. Higher doses are more likely to result in adverse events.

**Drug interactions.** The sedative effects of neurodepressants all are potentiated by meperidine. In addition, when given with phenothiazines, CNS toxicity and hypotension may occur. Interactions with monoamine oxidase inhibitors may be fatal and result in excitation, sweating, rigidity, hypertension or hypotension, and coma.

### Propofol

#### Pharmacology

Propofol is distributed rapidly and induces sedation within 30 to 60 seconds. The context-sensitive half-life is only 2 to 8 minutes. Metabolism is by hepatic conjugation with renal excretion of inactive metabolites. Propofol is a centrally acting neural depressant without any analgesic properties and rapidly crosses the blood-brain barrier to potentiate GABA activity.

#### Contraindications

Propofol is contraindicated in patients with known allergy to propofol.

#### Precautions and Adverse Reactions

The most important effects to be monitored with propofol are respiratory depression and apnea, occurring frequently with deep sedation. Hypotension is also common. Patients with ASA class 3 or higher, elderly patients, and patients using sedatives or opioid agents are at particular high risk for developing these cardiorespiratory complications. Apnea and hypotension can occur in 75% of patients. In endoscopic trials using propofol, ventilatory support was necessary in 10% of patients, although incidence of respiratory depression necessitating support was far greater in complex procedures requiring a cooperative patient.<sup>20</sup> Excitatory phenomena such as tremors, twitches, hypertonus, and hiccups can occur in 14% of patients. Rarely, pulmonary edema, hypertension, cardiac arrhythmias, bronchospasm, and laryngospasm have occurred. Pain at the injection site is the most frequent local complication and occurs in 5% to 50% of patients.<sup>21</sup>

#### Administration

Propofol has been given in endoscopic studies by repeated bolus injections or as an infusion. Propofol is usually administered as an initial bolus dose of 20 to 40 mg followed by maintenance doses of 10 to 20 mg to attain the required level of sedation. Alternatively, propofol can be infused at a dose of 0.5 to 1.0 mg/kg over 1 to 5 minutes to induce deep sedation, followed by maintenance infusion at a dose of 1.5 to 3 mg/kg per hr. For anything other than very short procedures, administration of propofol as an infusion is preferable because this produces better steady-state levels and more stable operating conditions.

#### Interactions

The sedative effect of propofol is enhanced by other sedative agents and analgesics.

### Flumazenil

#### Pharmacology

Flumazenil is an imidazobenzodiazepine and antagonizes benzodiazepines through competitively inhibiting central receptors. Its effects are rapid, within 30 to 60 seconds, and it has an elimination half-life of 53 minutes. Clearance is entirely hepatic, where it is conjugated to form inactive metabolites.

#### Contraindications

Flumazenil should not be given to patients with known sensitivity to flumazenil.

#### Precautions and Adverse Reactions

Care should be taken when administering flumazenil to patients with known benzodiazepine dependence because this may precipitate withdrawal or convulsions. Consideration should be given to the possibility of re sedation and respiratory depression following the use of flumazenil. Patients should be monitored for an appropriate period based on the dose and duration of effect of the benzodiazepine used. Despite the use of reversal agents, patients should still be given postprocedural warnings, as previously described. Flumazenil is not recommended in epileptic patients taking benzodiazepines because this may give rise to convulsions. Seizures have been reported in patients with epilepsy and hepatic impairment.

#### Interactions

Flumazenil also blocks the effects of nonbenzodiazepines acting on benzodiazepine receptors such as zopiclone.

#### Administration

The recommended initial dose is 0.2 mg administered intravenously over 15 seconds. This dose can be repeated using 0.1-mg doses every 60 seconds to achieve reversal to a total dose of 2 mg.

### Naloxone

#### Pharmacology

Naloxone is a competitive antagonist at opiate receptor sites and can reverse the sedative and respiratory effects of opiates. The effects of intravenous naloxone are apparent within 2 minutes, and a single dose from an ampule of 0.2 mg lasts 20 to 30 minutes. The effects of meperidine and other opioids last longer than this, therefore repeated doses of naloxone may need to be given. Naloxone is conjugated in the liver with renal excretion of the metabolites. Elimination half-life is 60 to 90 minutes.

#### Contraindications

Naloxone should not be administered to patients with known hypersensitivity to this medication.

#### Precautions and Adverse Reactions

Care is required in patients who are dependent on opiates because naloxone can precipitate withdrawal syndrome. A rapid reversal of opioids can induce catecholamine release and cause excitation, ventricular arrhythmias, hypotension, pulmonary edema, convulsions, and death. Care should be used in patients with preexisting cardiac abnormalities.

#### Administration

Naloxone can be given intravenously or intramuscularly at an initial dose of 0.4 to 2 mg. Doses can be repeated at 2- to 3-minute intervals until a total dose of 10 mg is reached.

### ACKNOWLEDGEMENT

We would like to thank Drs. Matthew R. Banks, George J.M. Webster, and Liang H. Wee for their valuable book chapter on the same topic in the previous edition of *Clinical Gastrointestinal Endoscopy*. The framework from their excellent chapter was used to write the current version of this book chapter.

## INTRODUCTION

Correct patient preparation is essential for all endoscopic procedures because it contributes significantly to the safety and success of the procedure. Many requirements must be considered during the preparatory phase; patient preparation is not limited to statements regarding fasting or how to complete a bowel preparation. The clinician must consider issues such as timing and patient-specific factors that must be taken into account when preparing for an endoscopic procedure. If the patient has had this type of information explained, he or she is more likely to comply with preparation instructions in a safe manner. As part of this phase and as part of the explanation about what the procedure involves, it is also necessary to explain potential risks and complications. All this communication with the patient contributes to the process of obtaining informed consent, which is a crucial part of the preparation process.

## INFORMED CONSENT

The process of informed consent varies from country to country. In many parts of Europe, a formal consent is not required before

endoscopic examinations. If the patient comes to have the procedure performed, these systems assume an implied consent. In other parts of the world, such as the United States and Australia, the consent process is a very detailed and potentially complex process that requires considerable attention by the endoscopist (see Chapter 10).

## GENERAL INFORMATION ABOUT PATIENT PREPARATION

Numerous aspects must be considered when preparing patients for endoscopic examinations, including the following:

- Understanding of the patient's particular clinical problem
  - Awareness of the patient's clinical history
  - Knowledge of the patient's recent (and past) medication history
  - Requirements of procedure-specific preparation
  - Requirements of patient-specific preparation
  - Informed consent
  - Postprocedure observation and discharge planning
- The endoscopist must have knowledge of the indication for the procedure because this determines not only what procedure is performed but also what interventions or treatment might be

### Abstract

In order for any endoscopic procedure to be safe and successful, appropriate informed consent, correct patient preparation, and awareness of patient-specific factors must be taken into account. Although informed consent varies from country to country, most would agree that the consent process should include a detailed explanation of indications, potential risks, and benefits of the procedure. The endoscopist's knowledge of procedural indication not only determines what procedure is performed but also what interventions or treatment might be required during the procedure. Understanding the patient-specific factors will enable the endoscopist to determine the proper preparation and any specific modifications that might be required for an individual patient. This information, in turn, allows the endoscopist to select the most appropriate type of sedation, bowel preparation, need for antibiotics, and discontinuation of antiplatelet and anticoagulation therapies for the patient. There are special circumstances where specific preparations are required to ensure the safety and success of the procedure, which include endoscopies for foreign body removal or food bolus impaction, as well as acute upper and lower gastrointestinal bleeding. The decision to discontinue antithrombotic or anticoagulation therapy is primarily based on a comparison of the risk of bleeding from an endoscopic intervention to the risk of a thromboembolic event. Preparation for patients with hemostasis disorders should be individualized and performed in close collaboration with an experienced hematologist. This chapter aims to outline important key steps in preparing patients for various endoscopic procedures, with detailed discussions regarding the use of prophylactic antibiotics and the management of antithrombotic and anticoagulation medications.

### Keywords

endoscopy  
patient preparation  
antibiotics  
antiplatelet therapy  
anticoagulants

required during the procedure. Implicit also is an understanding of the patient's clinical history and the results of any recent investigations. The preprocedure assessment must extend to the patient's past medical and surgical history, previous endoscopy results, current medical therapy (including over-the-counter and intermittent medications), and drug allergies. Specific clinical history such as diabetes, a personal or family history of bleeding disorder, anesthetic reactions, or previous adverse reactions to other medical interventions (including reactions to radiologic contrast agents) should also be considered. Armed with this information, the endoscopist is able to determine the proper preparation and any specific modifications regarding sedation that might be required for the individual patient (see Chapter 7).

After the procedure preparation, risks, and potential complications have been discussed, the next phase of the explanatory process is to discuss discharge guidelines. Most endoscopic examinations are performed as day procedures, and frequently patient sedation is administered. Most institutions require that sedated patients are discharged in the care of a responsible person who not only can supervise transportation of the patient home but who also is able to respond to any delayed complications or difficulties. The level of postprocedure supervision depends on the type of intervention and sedation, specific patient factors such as mobility and age, and other factors such as geographic isolation. These issues must be brought to the patient's attention before the procedure so that proper planning can occur. Difficulties with discharge arrangements should always be resolved before the endoscopic procedure and never left to be discussed after the procedure has been performed. Although the previous process may seem cumbersome, there are significant advantages for the patient and the endoscopist, such as the following:

- Ability to obtain informed consent
- Proper patient preparation
- Greater patient confidence with preparation
- Decreased failure of patient to attend endoscopic examination
- Correct procedure being performed
- Improved diagnostic yield
- Decreased patient anxiety and potentially improved patient tolerance of the procedure
- Improved discharge outcome

## ROUTINE LABORATORY TESTING BEFORE ENDOSCOPIC PROCEDURES

Routine preprocedure laboratory testing is the practice of ordering a set panel of tests for all patients undergoing a given procedure, irrespective of specific information obtained from the history and physical examination. There are insufficient data to determine the benefit of routine laboratory testing before endoscopic procedures.<sup>1</sup> Most studies indicate that physicians overuse laboratory testing and that routine preoperative screening tests are usually unnecessary. In one large study, only 40% of preoperative tests were done for a recognizable indication, and less than 1% of the tests revealed abnormalities that would have potentially influenced perioperative management.<sup>2</sup> Moreover, no adverse events were attributable to the identified laboratory abnormalities. An evaluation of routine laboratory testing in the periendoscopic period should consider the frequency of abnormal test results within a given population, the accuracy of the tests, the risks of the planned procedure, the use of moderate sedation versus anesthesia, and whether an abnormal result will affect the decision

to perform endoscopy or alter periprocedural management or outcome. Individual patient and procedure risks should be factored into the decision to perform periendoscopic laboratory tests. The cost of screening and the expense of follow-up testing to evaluate often minor abnormalities that seldom improve patient care must also be considered. Furthermore, falsely abnormal test results may unnecessarily delay endoscopy and subject the patient to additional risks, with untoward health and economic consequences.

## PREPARATION FOR ENDOSCOPY AND ENTEROSCOPY

Patients should not eat solid food for 6 to 8 hours or drink clear fluids for at 2 to 4 hours before an elective endoscopy.<sup>3</sup> If a delay in gastric emptying is known or suspected, longer fasting or a period of a fluid-only diet should be considered. Many centers use prokinetic agents to speed gastric emptying in patients when fasting time is inadequate (see subsequent section on *special circumstances*). In situations in which there is a delay in gastric emptying or in which there is inadequate fasting time, there is a significant risk of pulmonary aspiration, and airway protection with airway intubation should be considered. Normally, it is acceptable for patients to take their usual medicines with a sip of water before endoscopy. Special consideration must be given to patients taking anticoagulant medication or medication to treat diabetes (see subsequent section on *Special Circumstances*).

If a bleeding disorder is suspected or known, tests to evaluate this and direct therapy are indicated. Similarly, if the patient's clinical condition is unstable or indicates that an abnormality in the blood tests is likely to be present, appropriate testing and correction of relevant abnormalities is indicated. Preparation for antegrade enteroscopy is the same as described earlier. If retrograde enteroscopy is to be performed, preparation requirements are the same as for colonoscopy.

## PREPARATION FOR ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

The preparation of patients for endoscopic retrograde cholangiopancreatography (ERCP) is similar to the preparation for endoscopy.<sup>3</sup> Generally, patients undergoing ERCP almost always require sedation and the duration of the procedure is longer; this should be taken into account for purposes of discharge planning. Patients with suspected or proven biliary or pancreatic duct obstruction are generally given prophylactic intravenous antibiotics if there is a clinical suspicion of inadequate duct drainage (Table 8.1). Antibiotics may also be given in patients with sclerosing cholangitis and in patients after liver transplantation. Before ERCP, it is important to determine if the patient has a known history of reaction to iodinated contrast agents. Although reaction to the contrast agent in allergic patients during ERCP is rare, it is generally considered appropriate to administer prophylactic steroids, often in combination with an intravenous antihistamine agent. In severe cases, enlisting support of an anesthetist in case of a reaction is a prudent precaution. The use of a noniodinated contrast agent is an additional strategy.

Because ERCP is performed with radiologic imaging of the abdomen, patients who have had recent barium studies or other oral contrast agents should be checked to ensure that the field of view is clear for the ERCP to be successfully completed. If there is residual contrast material in the gut, a formal bowel

**TABLE 8.1 Antibiotic Prophylaxis and/or Treatment to Prevent Local Infections**

Patient Condition	Procedure	Need for Antibiotic Prophylaxis	Goal of Antibiotic Prophylaxis
Biliary obstruction without cholangitis	ERCP with complete drainage ERCP with incomplete drainage	Not recommended Recommended; continue antibiotics after procedure	Not applicable (NA) Prevention of cholangitis
Solid lesion in the upper and lower GI tract	EUS-fine-needle biopsy	Not recommended	NA
Cystic lesion in mediastinum or pancreas	EUS-fine-needle aspiration	Suggested	Prevention of cyst infection
All patients	PEG or PEJ insertion	Recommended	Prevention of peri-stomal infection
Cirrhosis with acute GI bleeding	All patients, regardless of the nature of endoscopic procedure	Recommended on admission	Prevention of infectious events and reduction of mortality
Synthetic vascular graft and other nonvalvular cardiovascular devices	Any endoscopic procedures	Not recommended	NA
Prosthetic joints	Any endoscopic procedures	Not recommended	NA
Peritoneal dialysis	Lower GI endoscopy	Suggested	Prevention of peritonitis
Solid malignancy of upper GI tract	EUS guided fiducial insertion	Suggested	Prevent seeding infection at insertion site

ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound; GI, gastrointestinal; PEG, percutaneous endoscopic gastrostomy; PEJ, percutaneous endoscopic jejunostomy.

Adapted from ASGE Standards of Practice Committee, Khoshab MM, Chithadi KV, et al: Antibiotic prophylaxis for GI endoscopy. *Gastrointest Endosc* 81(1):81-89, 2015.

preparation may be required. Women of childbearing age must be asked if they are pregnant. If there is uncertainty, the ERCP may need to be deferred until a pregnancy test can be done. If ERCP is considered necessary in a pregnant woman, appropriate lead shielding of the lower abdomen is recommended to protect the fetus. Similarly, pelvic shielding is appropriate for any premenopausal woman.

No data support routine blood tests before diagnostic ERCP, and screening tests are generally not required. If a bleeding disorder is suspected or known, tests to evaluate this and direct therapy are indicated. Similarly, if the patient's clinical condition is unstable or indicates that an abnormality in the blood tests is likely to be present, appropriate testing and correction of relevant abnormalities is indicated. In patients presenting for ERCP with a history or signs of biliary obstruction, the possibility of disordered coagulation exists. Correction of this type of abnormality before the procedure is appropriate.

The European Society of Gastrointestinal Endoscopy now recommends routine rectal administration of 100 mg of diclofenac or indomethacin immediately before (or after) in all patients without contraindication to the medication.<sup>8</sup>

## PREPARATION FOR COLONOSCOPY

Of all endoscopic procedures, the quality of the preparation before colonoscopy has the greatest effect on the outcome of the procedure.<sup>9</sup> The preparation is often regarded as the most unpleasant part of colonoscopy, and many patients are more concerned about this aspect than having the procedure performed. It is vital that the patient be given detailed verbal and written instructions to complete the preparation safely. If the correct preparation is not followed, the procedure usually has to be deferred. Good bowel preparation is essential to provide an optimal view for colonic examination and to minimize the risk of colonic trauma during the procedure resulting from a poor view. The method of administration and types of bowel preparation are discussed in detail in the next chapter (Chapter 9).

To achieve an optimal preparation, a careful patient assessment is needed to determine which bowel cleansing agent should be used and what modifications to the patient's diet and regular medications are required. The addition of simethicone to the bowel preparation does not improve cleansing but does reduce bubbles, which may improve the endoscopic view.<sup>10</sup> As part of the preparation, most patients are advised to have only a clear liquid diet for 24 hours before the examination.<sup>11</sup> Routine blood testing before colonoscopy is not required. Management of patients taking antiplatelet and anticoagulation medications should be carefully considered before the examination to minimize the risk of procedure-related bleeding (see later guidelines). In addition, any medication that might be associated with constipation should be temporarily stopped to facilitate the bowel cleansing process. In particular, oral iron can make the stool black and viscous, and iron should be stopped at least 5 days before the colonoscopy.<sup>12</sup> Last, specific instructions should be given to diabetic patients who are taking oral hypoglycemic medications or insulin to avoid periprocedural hypoglycemia.

Intravenous sedation is administered to most patients who undergo colonoscopy. It is necessary for the patient to fast before the procedure to reduce the potential for aspiration. The duration of fasting can be comparatively brief because the patient will have been on clear fluids only for 24 hours before the procedure while undergoing bowel preparation. A fasting time of 2 to 4 hours is generally considered adequate.

There are many independent predictors for a potential inadequate bowel preparation, such as a late colonoscopy start time; failure to follow preparation instructions; inpatient status; procedural indication of constipation; use of drugs that impair gut motility (e.g., tricyclic antidepressants, calcium channel blockers, iron); male gender; and a history of cirrhosis, stroke, dementia, obesity, or diabetes mellitus.<sup>13-15</sup> A prior history of failed colonoscopy preparation is also highly predictive of a failed second or subsequent attempt at preparation.<sup>16</sup> In these various patient groups, a more prolonged bowel preparation may be required. Other options to improve the quality of the preparation include abstinence from dietary fat for 1 week and a morning

procedure time. In patients who develop nausea, vomiting, or excessive bloating and patients who do not tolerate the preparation, one of the following measures can be used:

- Stop the preparation early if a clear fecal fluid output is achieved
- Interrupt the preparation temporarily for 1 to 2 hours and then resume
- Use a trial dose of metoclopramide or another prokinetic agent
- Chill the bowel preparation solution (very cold solution is not recommended)
- Add clear, sugar-free flavor enhancers or lemon juice (avoid red colors)
- Slow the rate of consumption of the solution

### PREPARATION FOR FLEXIBLE SIGMOIDOSCOPY

Preparation before flexible sigmoidoscopy generally requires cleansing of only the left colon.<sup>5</sup> In most cases, this cleansing can be achieved by administering one or two enemas 1 hour before the procedure. Several types of enemas are available:

- Microlax enema (sodium citrate 450 mg, sodium lauryl sulfoacetate 45 mg, and sorbitol 3.125 g)
- Fleet enema (sodium phosphate)
- Tap water enema
- G&O enema (three parts glycerin, three parts olive oil, and three parts water)

A more extensive bowel preparation may be required in severely constipated patients or in patients in whom a therapeutic procedure is required, such as polypectomy or argon plasma coagulation therapy. In these cases, 2 L of polyethylene glycol (PEG)-based bowel preparation with 24 hours of clear fluid may be adequate. In contrast, bowel preparation may be unnecessary in patients with active colitis or watery diarrhea. Generally, patients undergoing flexible sigmoidoscopy do not require intravenous sedation. If sedation is required, the patient should be advised to follow a protocol similar to other endoscopic procedures requiring sedation.

### PREPARATION FOR ENDOSCOPIC ULTRASOUND

Patient preparation for endoscopic ultrasound (EUS), including the dietary guidelines, is similar to preparation for upper gastrointestinal (GI) endoscopy.<sup>1</sup> In patients in whom a biopsy or therapeutic intervention is considered necessary, a platelet count and coagulation studies may be appropriate before the procedure if a bleeding disorder is suspected. In addition, antiplatelet and anticoagulation therapies must be reviewed, and if EUS-guided biopsy is likely to be performed, appropriate modification or cessation of these agents is necessary given that EUS-fine-needle aspiration (FNA) is a high-risk procedure for bleeding (see later discussion). Diagnostic EUS is considered a low-risk procedure and thus antiplatelet and anticoagulation therapies can be continued. For those who are on double-antiplatelet therapy for coronary stent(s), EUS-FNA can be performed with cessation of clopidogrel but continuation of aspirin. A 2017 retrospective study indicated that the risk of bleeding in patients who underwent EUS-FNA while on aspirin was not significantly higher than those without aspirin use (1.6% vs. 1.0%).<sup>11</sup>

Antibiotic prophylaxis is not generally required unless FNA of a cystic lesion or fiducial insertion is being performed (see Table 8.1). FNA of cystic lesions is considered high risk for

infection, and antibiotics are recommended. Available limited data indicated that the risk of infection after fiducial placement varies between 0.6% and 1.6%.<sup>12,13</sup> Given the inability to remove these markers after implantation, antibiotic prophylaxis is generally recommended and adopted by most centers.<sup>14</sup> In contrast, FNA of solid lesions in the upper GI tract<sup>15,16</sup> or in the lower GI tract<sup>17</sup> has been shown to be a low-risk procedure and does not warrant antibiotic prophylaxis. The use of antibiotic prophylaxis in EUS-guided celiac plexus block or neurolysis has not been established, as infectious complications after this procedure are rare.<sup>18</sup>

### PREPARATION FOR CAPSULE ENDOSCOPY

Optimizing conditions for capsule endoscopy continues to be an area of interest. Most centers prefer a slightly longer fasting time than for routine endoscopy. Generally, clear fluids are given after lunch on the day before the examination, and the patient fasts for 12 hours before the examination is scheduled to begin. No medication should be taken within 2 hours of ingestion of the capsule. In some centers, 2 L of a PEG-based bowel preparation regimen is given before the patient begins the 12-hour fast.<sup>19,20</sup> This additional step might be particularly important if the patient has had a recent barium study or has had some other form of oral radiologic contrast agent. Some units ask the patient to ingest a small amount of simethicone preparation before the procedure to improve visual quality, as well as a prokinetic such as metoclopramide.<sup>21</sup> The use of a purgative preparation may improve the quality of the small bowel images obtained during the capsule endoscopy study and increase the diagnostic yield.<sup>22</sup> This benefit has not been confirmed in other studies. The purgative preparation does not seem to influence completion rate of the study, however. The optimal preparation regimen is not yet established, so instructions may be individualized for the patient. It is prudent to review the patient's medications and consider withholding any medication that might slow GI motility. Iron supplements should be stopped at least 3 days before the examination.

### PREPARATION FOR ENDOSCOPIC PROCEDURES IN PATIENTS WITH DIABETES

There are no controlled trials to guide preparation for endoscopic procedures in diabetic patients.<sup>23</sup> The approach to these patients must be individualized, and factors such as usual glycemic control and the patient's ability to manage his or her diabetes are important considerations. There are no specific requirements in diabetic patients who are controlled on diet alone. In patients taking oral hypoglycemic agents, medications are generally withheld during preparation for the procedure. During this time, the patient must monitor his or her serum glucose and be able to manage or get assistance if there is evidence of progressive hyperglycemia. Hypoglycemia is managed with sugar-containing clear fluids or candy. In patients taking insulin, dose reduction while undergoing the preparation is normal. For upper GI procedures, the usual dose may be given the evening before the procedure, but only half the dose is given on the morning of the examination. The remaining dose can be given, if appropriate, after the procedure has been completed.

Insulin-dependent diabetics undergoing preparation for colonoscopy should have their diabetic treatment individually modified with clear instructions provided as to how hypoglycemia

and hyperglycemia should be managed. Diabetic patients should preferentially be scheduled for a morning procedure and ideally be the first case for the day. During the preparation, the patient must be advised to monitor serum glucose regularly. Patients with brittle diabetic control, patients unable to manage hypoglycemia or hyperglycemia, and patients with significant other comorbidity may need medical or nursing supervision during bowel preparation.

## SPECIAL CIRCUMSTANCES

### Preparation for Endoscopy in Case of Ingestion of a Foreign Body or for Food Bolus Obstruction

Ingestion of foreign bodies occurs mainly in children and mentally disabled patients. Food bolus obstruction is relatively common in adults, particularly with the increasing incidence of eosinophilic esophagitis.<sup>31,32</sup> Endoscopic assessment and removal is the main modality of treatment for objects below the level of the crico-pharyngeal muscle. The nature of the patient's symptoms and what has been ingested determines the urgency of the procedure. Emergency procedures should be performed for patients who are unable to swallow their saliva, patients with sharp objects (e.g., fish bones, pins, dentures, razor blades), and patients with impacted disk batteries.<sup>33,34</sup> The procedure is probably technically easier if performed early. Plain x-rays of the chest and neck may be advisable before the endoscopic procedure if the nature of the object or the site of obstruction is unclear from the history. The x-ray film may also show ectopic gas patterns to indicate a silent perforation. Oral radiologic contrast material is generally best avoided because of the risk of aspiration and because it may obscure the endoscopic field.<sup>35,36</sup>

With regard to food bolus impaction, glucagon or another prokinetic can be given while the patient is waiting for endoscopy, but this is usually unsuccessful and should not delay endoscopy.<sup>37,38</sup> Special attention should be given to airway protection to avoid the risk of airway obstruction during the procedure. Continuous oral suction and the availability of a laryngoscope are also important. General anesthesia with endotracheal intubation is usually required if airway protection is needed. Whereas the literature suggests that airway intubation is required in less than 25% of cases,<sup>39</sup> it is probably performed more frequently than not in modern endoscopic units and is probably a prudent precaution. An alternative strategy to protect the airway is the use of an esophageal overtube, but this should be used with caution due to the risk of perforation. General anesthesia with muscle relaxation often facilitates removal of difficult or large items, particularly as they pass through the upper esophageal sphincter; this is particularly true for swallowed dentures (see Chapter 22).

### Preparation for Endoscopy in Patients With Upper Gastrointestinal Bleeding

Preparation of an acutely bleeding patient for endoscopy requires additional precautions and care. The first step is to ensure that the patient is adequately resuscitated because any subsequent endoscopy is best performed when the patient is hemodynamically stable. Volume replacement and correction of any coagulation or platelet function disturbance are important. If there is evidence of ongoing bleeding, urgent endoscopy with airway protection, even in an unstable patient, may be the best way of getting better clinical control of the situation. If time permits, a 6-hour fast is desirable because this would improve the endoscopic view.

However, a fast is often not practical, particularly if there is evidence of active bleeding. Sometimes gastric lavage can be used to empty the stomach of blood before endoscopy is performed. Care must be taken not to suck too aggressively with the gastric lavage tube because significant mucosal trauma can occur, and this can make interpretation of the subsequent endoscopic findings difficult. Available data, including from a randomized, placebo-controlled study, have demonstrated the benefit of an intravenous dose of erythromycin given 2 hours before endoscopy to improve endoscopic view in patients with upper gastrointestinal bleeding.<sup>31</sup> Three meta-analyses have also concluded that the administration of intravenous erythromycin is beneficial in this situation.<sup>32-34</sup>

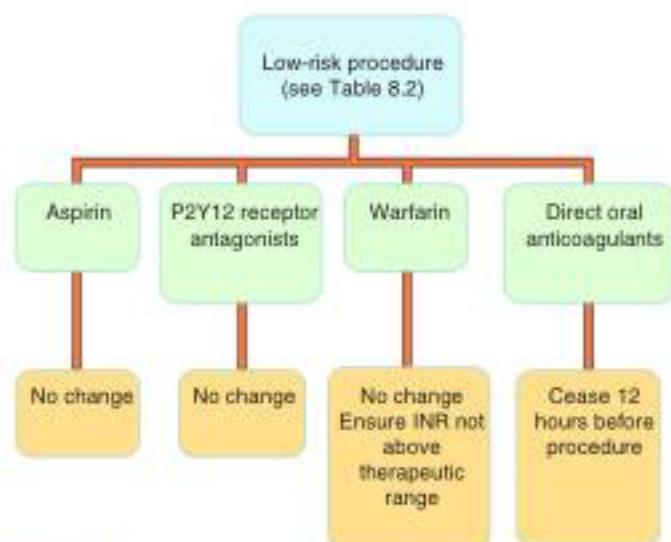

Endoscopy in patients with upper GI bleeding is usually performed after the patient has received intravenous sedation.<sup>35</sup> General anesthesia and endotracheal intubation should be considered in patients with active hematemesis or if there is a perceived increased risk of aspiration. If the patient is suspected of having a bleeding peptic ulcer, an intravenous proton pump inhibitor (PPI) should be given before the endoscopy. Studies have suggested that a PPI can significantly improve outcome in these patients.<sup>36-38</sup> Similarly, patients suspected of having variceal bleeding may benefit from an octreotide or terlipressin infusion<sup>39-41</sup> (see Chapter 15). Patients who present with suspected variceal bleeding due to known chronic liver disease should receive preprocedure intravenous antibiotics (see subsequent section on antibiotic prophylaxis).

### Preparation for Colonoscopy in Patients With Lower Gastrointestinal Bleeding

In patients with lower GI bleeding, colonoscopy is the procedure of choice to identify the site of bleeding and, in some circumstances, allows therapeutic intervention (see Chapter 16).<sup>42</sup> Before the procedure, patients should be resuscitated, and their general condition should be stabilized. Routine blood tests and coagulation profiles are generally performed in patients with upper GI bleeding, and these should be corrected if abnormal. Generally, colonoscopies in patients with lower GI bleeding are performed on a semi-urgent basis, and when the patient is hemodynamically stable to allow time for some form of bowel preparation. The view at colonoscopy if the patient is actively bleeding is often a problem in procedures performed urgently, although some studies suggest that urgent colonoscopy is not only technically possible and safe but also effective in controlling bleeding.<sup>43,44</sup> Blood itself is a cathartic; some clinicians perform the procedure in an unprepared bowel.<sup>45</sup> Other clinicians preferring a bowel preparation generally give 4 L of PEG over 4 hours before the procedure.<sup>34,46,47,48</sup> This solution can be given orally or via a nasogastric tube. In elective procedures, the colon can be prepared in a standard fashion. Because these patients are at higher risk of a disturbance of intravascular volume, it is generally advisable to avoid sodium phosphate-based preparations. A prokinetic agent may facilitate the bowel preparation. In general, patients should not have barium studies before colonoscopy because it would interfere with the view and may obscure flat mucosal lesions such as angiodysplasia. If an obstructive lesion is suspected, a clear water-soluble contrast agent such as Gastrografin should be used.

### Antiplatelet and Anticoagulation Therapy

Endoscopic procedures are being performed more frequently in patients who are receiving antiplatelet and/or anticoagulant

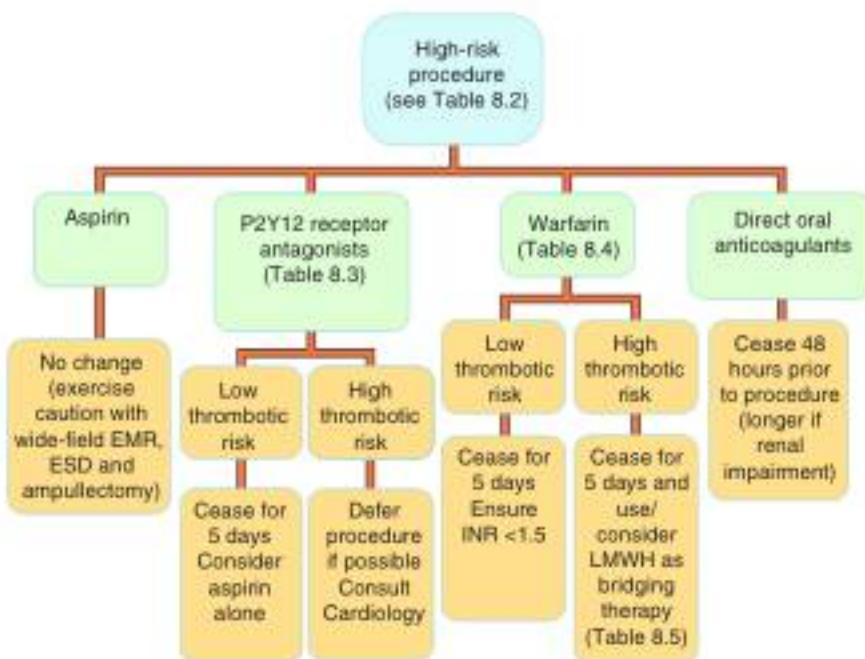

**FIG 8.1** Low-Risk Endoscopic Procedure. INR, international normalized ratio.

**TABLE 8.2** Endoscopic Procedures Considered to Be at Low- and High-Risk of Bleeding

Low Risk	High Risk
Diagnostic procedures ± biopsy	Polypectomy
ERCP without sphincterotomy	ERCP with sphincterotomy/ampullectomy
Biliary or pancreatic stenting	Dilation of strictures
Diagnostic EUS	Therapy of varices
Enteroscopy	PEG or PEJ insertion
Argon plasma coagulation	EMR/ESD
Barrett's ablation therapy	EUS with FNA
	Esophageal/enteral/biloma stent (controversial)
	Cystogastrostomy

EMR, endoscopic mucosal resection; ERCP, endoscopic retrograde cholangiopancreatography; ESD, endoscopic submucosal dissection; EUS, endoscopic ultrasound; FNA, fine needle aspiration; PEG, percutaneous endoscopic gastrostomy; PEJ, Percutaneous endoscopic jejunostomy (direct).

**FIG 8.2** High-Risk Endoscopic Procedure With Low- or High-Risk Thrombotic Condition. EMR, endoscopic mucosal resection; ESD, endoscopic submucosal dissection; INR, international normalized ratio; LMWH, low molecular weight heparin.

therapy. Management of these patients and their medications in the perioperative period requires clinical judgement and an understanding of risks involved; the latter includes both the risks of hemorrhage when performing endoscopic procedures on antiplatelet or anticoagulant therapy and the risks of thromboembolism and other adverse events when ceasing these medications (Figs. 8.1 and 8.2). Patients will need an individualized assessment, and it is not possible to give guidance to cover all situations.

All endoscopic procedures have an inherent risk of bleeding. Minor bleeding is common; however, clinically relevant bleeding, defined as bleeding requiring specific intervention, unplanned

admission to hospital, or blood transfusion, should be rare. Traditionally, procedures have been divided into those at low and high risk for hemorrhage (Table 8.2).<sup>4,50</sup> The risk of thromboembolism from conditions treated by antiplatelet agents is summarized in Table 8.3 and from conditions treated by warfarin are summarized in Table 8.4. Both these aspects need to be considered before a decision is made to cease antiplatelet or anticoagulant medication. In some high-risk situations, these medications cannot be ceased without very significant consequences. The recommendations made in this chapter are in keeping with the 2016 guidelines from the American Society for Gastrointestinal Endoscopy (ASGE),<sup>49</sup> the British Society of

**TABLE 8.3 Low- and High-Risk Conditions for Ceasing Clopidogrel**

Low Risk	High Risk
Ischemic heart disease without stent	Bare metal stent (within 1 month)
Cerebrovascular disease	Drug-eluting stent (within 12 months)
Peripheral vascular disease	

**TABLE 8.4 Low- and High-Risk Conditions for Ceasing Warfarin**

Low Risk	High Risk
Prosthetic (metal) aortic valve	Prosthetic (metal) mitral valve
Prosthetic (xenograft) valve	Prosthetic (metal) valve and AF or prior thromboembolic event
AF without valvular heart disease	AF and valvular heart disease (especially mitral stenosis)
Over 3 months since VTE	Under three months since VTE
Thrombophilia syndromes	

AF, atrial fibrillation; VTE, venous thromboembolic event.

## RISK STRATIFICATION

For all endoscopic procedures there is a risk of intraprocedure or postprocedure bleeding. Many patients who present for elective endoscopic procedures are taking antithrombotic therapy to reduce the risk of thromboembolic events associated with conditions such as atrial fibrillation, acute coronary syndromes, deep vein thrombosis (DVT), hypercoagulable states, endoprostheses, etc. Recent guidelines summarized in this document consider the risk of bleeding from an endoscopic intervention versus the risks of antithrombotic drug cessation. The recommendations are mostly supported by clinical evidence, but in some cases only expert opinion is available to provide a best guess on the risk analysis of bleeding versus thrombosis. Many experts also recognize that bleeding is rarely fatal whereas the consequences of a major thromboembolic event can have very serious and lifelong effects on the patient. When considering discontinuing antithrombotic therapy, it is crucial to consider patient preference in addition to clinical opinion. A postpolypectomy hemorrhage might be considered a better outcome than a major CVA with permanent disability from the patient's perspective.

### Bleeding: Low-Risk Procedures

These are generally diagnostic procedures with or without biopsy (see Table 8.2). ERCP without sphincterotomy but with stent insertion, argon plasma coagulation, and Barrett's ablation therapy are also categorized as low-risk procedures. Aspirin does not increase the risk of clinically significant bleeding following low-risk endoscopic procedures, and thus can be continued (see Fig. 8.1). Data regarding the bleeding risk during low-risk endoscopic procedures when patients are on P2Y12 receptor antagonists (clopidogrel, prasugrel, ticagrelor, ticlopidine) are limited. The

previous recommendations of stopping P2Y12 receptor antagonists for low-risk procedures were based indirectly on data derived from surgical procedures (see Fig. 8.1). It remains common practice in patients taking dual antiplatelet agents to consider continuing aspirin and ceasing the P2Y12 receptor antagonist in the periprocedural period. In a systematic review of 161 reported cases of late drug-eluting stent thrombosis (> 30 days but < 1 year after stent placement) and very late drug-eluting stent thrombosis (> 1 year after stent placement), patients who discontinued both aspirin and a P2Y12 receptor antagonist had a median time to event of 7 days. In those who discontinued P2Y12 receptor antagonist but remained on aspirin, the median time to an event was 122 days. There were a total of six cases (6%) of stent thrombosis within 10 days of P2Y12 receptor antagonist cessation, suggesting that short-term discontinuation between 30 days and 1 year from drug-eluting coronary stent placement (late stent thrombosis) might be relatively safe but still carry some risk. The British and European guidelines more definitively state that P2Y12 receptor antagonists can be continued for low-risk procedures.

There are no data regarding bleeding risk in patients on low molecular weight heparin (LMWH) undergoing low-risk procedures. Decision making should therefore be individualized. For low-risk procedures, it can probably be continued (see Fig. 8.1).<sup>51</sup> Similarly, patients taking warfarin can continue their medication for low-risk procedures, providing the international normalized ratio (INR) is in the therapeutic range. The data to support this recommendation are, however, weak.

Advice on the use of direct oral anticoagulants (DOACs), such as dabigatran, rivaroxaban, and apixaban during low-risk procedures is difficult. Given these new anticoagulants do not need blood monitoring for their therapeutic range, they are increasingly used for prevention of: (1) venous thromboembolic events after major orthopedic surgery (hip and knee replacement); (2) stroke and systemic embolus in nonvalvular atrial fibrillation; and (3) DVT/pulmonary embolism recurrence. Clinicians should be cautious, as the degree of anticoagulation cannot be assessed, and the availability of reversal agent(s) are currently limited. In general, the peak anticoagulant effect of DOACs is between 2 and 6 hours after oral ingestion; this is prolonged in patients with renal impairment.<sup>52</sup> This is because DOACs, especially dabigatran, are cleared predominantly by the kidneys. Dabigatran also has limited bioavailability, and high concentrations of the drug may be found in the stool. This may cause a local bowel wall effect and account for reports of increased risk of lower GI bleeding in some studies. Given these factors, the general advice is to omit DOACs on the morning of a low-risk procedure<sup>53</sup> (see Fig. 8.1).

### Bleeding: High-Risk Procedures

Aspirin does not increase the risk of clinically significant bleeding following high-risk endoscopic procedures, including procedures like colonic polypectomy and biliary sphincterotomy (see Fig. 8.2). Cold snare polypectomy is associated with less delayed bleeding than diathermy-assisted polypectomy and may be a preferred resection technique where possible in patients taking aspirin. Advice regarding aspirin and wide-field endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD) is still not clear, and data are not conclusive. Similarly, the use of aspirin in patients undergoing ampullectomy should be cautious, as the risk of bleeding is significant, and informed consent is important.

P2Y12 receptor antagonists should be stopped for 5 days in patients undergoing a high-risk procedure who are considered at low thrombotic risk (see Fig. 8.2). As for low-risk procedures, it is recommended for patients taking dual antiplatelet agents to consider continuing aspirin and stopping the P2Y12 receptor antagonist 5 days prior to the procedure. There are recent data in a small number of patients showing an excessive bleeding risk when transbronchial lung biopsies are taken while patients are on clopidogrel (3.4% vs. 89%).<sup>30-31</sup> The risk of bleeding after transbronchial biopsy is not increased in patients taking aspirin. The latter finding is similar to the endoscopic data and, by extrapolation, clopidogrel should be used with great caution in patients undergoing high-risk procedures. If the thrombotic risk is high, then the procedure should be deferred, or, if not possible, bridging therapy with LMWH should be considered.

A significant risk of hemorrhage exists when high-risk endoscopic procedures are performed on patients taking warfarin. Published data in this area are limited given that anticoagulation is generally avoided when high-risk procedures are performed; however, one study did show a high rate of bleeding when colonic polypectomy was performed with patients on warfarin (0.8% vs. 10.8%; odds ratio [OR] 13.37).<sup>32,33</sup> There are also data showing a high risk (10% to 15%) of significant bleeding when performing an ERCP with sphincterotomy in patients where warfarin is restarted within 72 hours.<sup>34</sup> Guidelines suggest cessation of warfarin 5 days prior to a high-risk procedure allowing the INR to drift back to normal during this time (see Fig. 8.2). The INR preprocedure should be less than 1.5.<sup>35,36</sup> If the procedure is uneventful and the risk of postprocedure bleeding is considered low, the warfarin can be restarted immediately after the procedure. In patients with a high thrombotic risk, warfarin should be ceased and bridging therapy be given using a LMWH, which should be stopped 12 hours prior to the procedure. All patients should be advised that there is an increased risk of postprocedure hemorrhage compared to nonanticoagulated patients.

In patients who are taking DOACs and undergoing high-risk procedures, the DOACs should be ceased 48 hours prior to the endoscopic procedure<sup>36,37</sup> (see Fig. 8.2). For patients with impaired renal function, the drug should be stopped 72 hours prior to the procedure. In those who are still on the DOACs and require an emergency procedure, urgent consultation with a hematologist is essential.

### Postprocedure Therapy Resumption

If antithrombotic therapy is stopped prior to a procedure, then it is recommended the therapy be resumed within 24 to 48 hours after the procedure depending on the perceived bleeding and thrombotic risks.

### Risk of Thromboembolism

Extreme care must be taken in discontinuation of antiplatelet therapy for endoscopy in patients who have a cardiac stent, as the risk of coronary stent thrombosis can be as high as 29%, leading to myocardial infarction with a significant risk of death.<sup>43,50</sup> The risks apply to both bare metal and drug-eluting stents, but the period for which most risk is present differs. Clopidogrel should preferably not be stopped for at least 1 month after insertion of a bare metal stent. When clopidogrel is prescribed following placement of a drug-eluting stent, cessation of therapy should be discussed with the patient's cardiologist. In general, antiplatelet therapy (usually dual therapy) should not be stopped within 12 months. If clopidogrel is to be ceased, the duration

should be less than 7 days, and, in most cases, aspirin should be continued.

Cessation of warfarin results in varying risks of thromboembolism, depending on the underlying condition (see Table 8.4). The highest risk exists for conditions such as prosthetic heart valves and atrial fibrillation (AF) with high risk features; there is a risk of thromboembolism (3.6%) in these situations despite bridging therapy with LMWH. The risk of thromboembolism in patients undergoing endoscopy who have their anticoagulation adjusted for the procedure, ranges from 0.31% to 2.93%. The risk of thromboembolism in AF without anticoagulation ranges from 1.9% to 18.2% depending on concomitant risk factors.<sup>40,51</sup> The risk of discontinuing warfarin in the setting of treatment for venous thromboembolism is probably low, particularly if more than 3 months have passed since the event.

Given that DOACs are frequently used for low-risk thrombotic conditions, they can be safely stopped prior to high-risk endoscopic procedures without bridging therapy. If these drugs are prescribed for conditions outside these indications, individual consideration is needed in consultation with the prescriber of the relevant agent.

### Bridging Therapy (Table 8.5)

In patients with nonvalvular AF, bridging with LMWH is not required. In a 2015 large randomized controlled trial that examined the role of bridging therapy with heparin for endoscopic procedure in AF patients, bridging therapy was associated with an increased risk of major bleeding events (3.2% vs. 1.3% [placebo]) and a similar rate of thrombotic events (0.3% vs. 0.4%).<sup>52</sup> Thus, in uncomplicated AF, bridging therapy is not necessary. The proportion of high-risk AF patients, such as those with concomitant mitral stenosis or high CHADS2 (congestive heart failure, hypertension, age ≥ 75 years, diabetes mellitus, stroke [double weight]) score was small; therefore, a firm recommendation on no bridging therapy in these patients cannot be made and consultation with a cardiologist is recommended. In contrast, bridging therapy is usually required for patients with

**TABLE 8.5 Approach to Bridge Therapy for Warfarin**

Condition	Associated Diagnosis	Management
Atrial fibrillation	None	No bridge recommended
	CHA2DS2-VASc score < 2	
	Mechanical valves/mitral stenosis	Consider bridge therapy
	History of CVA CHA2DS2-VASc score ≥ 2	
Valvular heart disease	Bileaflet mechanical AVR	No bridge recommended
	Mechanical AVR and any thromboembolic risk factor	Bridge therapy recommended
	Older generation mechanical AVR	
	Mechanical mitral valve	

CHA2DS2-VASc = congestive heart failure, hypertension, age > 75 years (2 points), diabetes mellitus, stroke (2 points), vascular disease, age 65–74 years, sex category (i.e., female sex).

AF, atrial fibrillation; AVR, aortic valve replacement; CVA, cerebrovascular accident. Adapted from ASGE Standards of Practice Committee, Acosta RD, Abraham NS, et al: The management of antithrombotic agents for patients undergoing GI endoscopy. *Gastrointest Endosc* 83(1):3–16, 2016.

metal heart valves and appears safe and effective for this indication. Some patients with newer metal aortic valves may not require bridging therapy. In patients with a thrombophilia, the risk of thrombotic events after temporary cessation of anticoagulation therapy is minimal and bridging is therefore not required. Thrombophilia syndromes have been recently reclassified as low-risk conditions, especially factor V Leiden and F2G20210A thrombotic mutation. Even in patients with deficiencies of antithrombin and protein C or S, who are at a higher risk of thrombosis, bridging is not required in most cases.

#### Endoscopy Procedures in a Bleeding Patient on Antithrombotic Therapy

In general, performing endoscopic procedures in an acutely bleeding patient taking antithrombotic therapy is reasonable and safe. Patients taking antiplatelet agents who bleed can be given a platelet transfusion. Once bleeding is controlled, then the antiplatelet therapy can resume. Data suggests that for patients who develop bleeding from aspirin-related peptic ulcer disease, resumption of aspirin with concurrent PPI therapy is better than switching to clopidogrel alone for prevention of recurrent bleeding. Prompt resumption of antiplatelet therapy after cessation of bleeding is crucial, as the risk of rebleeding is not significantly increased, but there is a clear increase in 30-day mortality in patients where antiplatelet therapy was not restarted.

In patients taking warfarin, reversal of the INR to a range of 2.5 or less allows successful intervention and outcomes comparable to nonanticoagulated patients. Preprocedure INR does not appear to correlate with procedure outcome in various studies. The Rockall and Glasgow-Blatchford scores assessing rebleeding risk or outcome do not include INR in their calculations. The predominant clinical concern is how best to correct the thrombotic defect and how to balance this reversal against the preexisting thrombotic risks. In general, plasma products, platelet transfusions, clotting factors, and vitamin K have all been used to reverse antithrombotic agent effects. Which product to use and how aggressive therapy is given will depend on the severity of bleeding and the thrombotic risk, as well as consideration of how best to resume antithrombotic therapy once bleeding has been controlled.

In the event of massive bleeding in patients taking the DOACs, hemodialysis can be used. In clinical practice, however, such an unstable patient is unlikely to be able to tolerate hemodialysis. Urgent hematology review is recommended, and often clotting factors are used but their effectiveness is uncertain. Specific monoclonal antibodies have been developed as antidotes for the DOAC agents and can reverse the anticoagulant effects within minutes. At present, idarucizumab, a monoclonal antibody against dabigatran, is available for use in the United States and Europe, but not currently in Asia-Pacific regions. Antidotes to other DOAC agents are under development and the results of clinical trials are eagerly awaited.

#### Management of Disorders of Hemostasis Before Endoscopic Examinations

Management of patients with hemostasis disorders should be individualized and when possible should be in close collaboration with an experienced hematologist in a specialized center with a specialist coagulation laboratory. The endoscopist must assess the risk of bleeding based on the procedural risk and the severity of the underlying disorder of hemostasis and plan the endoscopic procedure accordingly.<sup>52</sup>

#### Von Willebrand's Disease

von Willebrand's disease (vWD) is the most common inherited disorder of hemostasis; therapy before endoscopic procedures depends on the type of vWD. For less severe type I disease, treatment with desmopressin (DDAVP) starting 1 hour before the procedure and once daily thereafter for 2 to 3 days is adequate for patients undergoing diagnostic procedures and mucosal biopsies. However, for therapeutic procedures, infusion of factor VIII 1 hour before the procedure to achieve a factor VIII activity of 0.80 to 1.20 U/mL is required. After the procedure, factor VIII activity of at least 0.30 to 0.50 U/mL must be maintained for up to 2 weeks to minimize the risk of rebleeding.<sup>53</sup> For more severe type II and type III disease, the same factor VIII replacement regimen is required for diagnostic (maintenance duration of 2 to 3 days) and therapeutic procedures (up to 2 weeks).<sup>53</sup>

#### Hemophilia A and B

Preprocedural assay of factor VIII or IX activity is essential to determine the dosage of replacement therapy in patients with hemophilia. Before the procedure, factor VIII infusion is required to achieve an activity of 0.80 to 1.20 U/mL. Postinfusion factor assay should be obtained to determine the patient's response to the infusion. For purely diagnostic procedures, no further infusion is required. If mucosal biopsies are performed, 75% of the initial dose should be given every 24 hours for an additional 2 to 3 days. If therapeutic procedures are performed, twice-daily factor VIII infusion is required to achieve a maintenance activity of 0.30 to 0.50 U/mL for up to 2 weeks. Adequate factor VIII maintenance activity must be confirmed by at least daily factor VIII assay. Indications for factor IX replacement are identical to the indications for factor VIII infusion except that the maintenance dose is administered at intervals of 24 hours because the half-life of factor IX is longer.<sup>53</sup>

#### Liver Disease

The possible hemostatic defects in patients with liver disease are coagulopathy and thrombocytopenia. Correction is usually not required for diagnostic endoscopic procedures, but most centers would consider correction if the INR is greater than 2.5. Correction is necessary if therapeutic maneuvers are needed. These recommendations are based on limited data. If high-risk procedures are done, correction of an INR to less than 1.5 is advisable;<sup>54</sup> this can be accomplished by a combination of fresh frozen plasma and vitamin K replacement. Correction of significant thrombocytopenia is discussed later under "Thrombocytopenia" subsection.

#### Renal Failure

The main hemostatic defect in patients with renal failure is an acquired qualitative platelet defect secondary to uremia. Bleeding complications in these patients undergoing renal biopsy, abdominal surgery, liver and bone biopsies, or tooth extraction are rare.<sup>55</sup> In addition, measurement of preprocedural bleeding time is not helpful because it does not predict outcome.<sup>56</sup> Platelet infusion is not routinely recommended, unless concurrent significant thrombocytopenia exists.<sup>55</sup> Because uremia is thought to be the cause of platelet dysfunction, dialysis with limited heparin shortly before high-risk procedures is recommended to reduce serum urea nitrogen to less than 50 to 75 mg/dL.<sup>53,55</sup>

### Thrombocytopenia

There are no prospective data on the need for prophylactic platelet transfusion, and the following guidelines have been based on decision analysis.<sup>33,34,37</sup> Platelet transfusion to increase the platelet count to greater than  $20 \times 10^9$  platelets/L is required for low-risk procedures, and a count greater than  $50 \times 10^9$  platelets/L is required for high-risk therapeutic procedures. For patients with immune thrombocytopenia, elective procedures should be postponed until an appropriate improvement in platelet count (20 to  $30 \times 10^9$  platelets/L) is observed with standard therapy. If endoscopic procedures cannot be postponed and immediate intervention is necessary, a platelet transfusion should be given just before the procedure.<sup>33</sup> If bleeding occurs after the procedure, further platelet transfusion should be given. Input from a hematologist is recommended if response to platelet transfusion is poor.<sup>33</sup>

## ANTIBIOTIC PROPHYLAXIS

Although endoscopic procedures within the GI tract can be associated with bacteremia, clinically significant complications from the bacteremia are rare. There are, however, specific high-risk procedures and high-risk patient conditions for which it is considered appropriate to use prophylactic antibiotics (see Table 8.1; adapted from the 2015 ASGE guideline). The major high-risk procedures are esophageal dilation, sclerotherapy of varices, percutaneous endoscopic gastrostomy insertion, ERCP in patients who have an obstructed pancreaticobiliary tract, or those with inadequate duct drainage on completion of the procedure. High-risk patient factors that warrant specific consideration for antibiotic prophylaxis include patients with cirrhosis and ascites, patients with primary sclerosing cholangitis, and those with a preexisting immune-deficiency condition. The choice of antibiotic to be used in the previously listed circumstances is beyond the scope of this chapter. Local guidelines should be followed, and microbiologic advice should be sought if necessary. Recent positive cultures, if available, should be taken into account when deciding on antibiotic regimens. In addition, many institutions modify recommendations depending on whether the patient is an existing inpatient or presents to the hospital from the community. If local guidelines are not available, international guidelines from the British Society of Gastroenterology (2009)<sup>38</sup> or the American Society of Gastrointestinal Endoscopy (2015)<sup>39</sup> can be used.

### Antibiotic Prophylaxis for Prevention of Infective Endocarditis

The practice of antibiotic prophylaxis in GI endoscopy to prevent infective endocarditis has previously been common. Antibiotic guidelines no longer recommend routine antibiotic prophylaxis for the prevention of infective endocarditis as has previously been suggested.<sup>33</sup> A consensus document has been published looking at the role of antibiotic prophylaxis for the prevention of infective endocarditis.<sup>33</sup> These guidelines were prepared in collaboration with many learned societies and advisory groups and have been broadly adopted internationally. The guidelines conclude that:

- Only an extremely small number of cases of infective endocarditis might be prevented by antibiotic prophylaxis.
- Antibiotic prophylaxis is not recommended based solely on an increased lifetime risk of acquisition of infective endocarditis.

- Administration of antibiotics solely to prevent endocarditis is not recommended for patients who undergo GI tract procedures.

- Antibiotic prophylaxis is reasonable only for patients with an underlying cardiac condition associated with the highest risk of an adverse outcome from infective endocarditis.

Antibiotic prophylaxis may be considered in very high-risk cardiac conditions. The cardiac conditions that are considered the highest risk for adverse outcome from endocarditis include the following:

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- Previous history of infective endocarditis
- Congenital heart disease
- Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or device during 6 months after the procedure
- Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device
- Cardiac transplant recipients who develop cardiac valvulopathy

The major ongoing challenge that exists with the introduction of these new guidelines is patient education, but, with time, patient acceptance is definitely increasing. Many patients remain anxious and require reassurance that their expected administration of antibiotics is no longer required.

If antibiotics are required, it is recommended that a single dose be given before the procedure. If the antibiotic inadvertently is not administered before the procedure, it may be given up to 2 hours after the procedure. The gut contains a wide variety of bacteria, but of these, Enterococci are the most likely to cause infective endocarditis. If an antibiotic is required for a high-risk patient, amoxicillin and ampicillin are the preferred agents for enterococcal coverage. Vancomycin (1 gm IV) may be used in patients who are allergic to penicillin. Vancomycin administration should be slow (maximum rate 10 mg/min) to avoid complications. If patients are already receiving antibiotics, a different class of agent should be chosen rather than increasing the dose of the existing treatment. Antibiotic prophylaxis is generally given intravenously. Intramuscular injections should be avoided in patients who are anticoagulated.

### Antibiotic Prophylaxis for Patients With Vascular Grafts and Other Implanted Devices

It has been suggested that some delayed infections of orthopedic, neurosurgical, and other prostheses may be due to bacteremia associated with endoscopic procedures.<sup>33</sup> However, the risk from endoscopic procedures is negligible compared with other daily activities associated with bacteremia, such as chewing, or oral hygiene measures such as toothbrushing. Any benefit of antibiotics to cover these activities would be outweighed by the adverse effects. The British Society of Gastroenterology, the ASGE, and the American Society of Colon and Rectal Surgeons do not recommend the use of antibiotics before endoscopy in patients with orthopedic prostheses, central nervous system vascular shunts, vascular grafts or stents, penile prostheses, intraocular lenses, pacemakers, or local tissue augmentation materials.

### Antibiotic Prophylaxis for Percutaneous Endoscopic Gastrostomy or Percutaneous Endoscopic Jejunostomy

A single dose of an appropriate antibiotic given 30 minutes before percutaneous endoscopic gastrostomy or jejunostomy insertion

is routinely recommended for all patients who are not already receiving antibiotics because the risk of peristomal wound infection is significantly reduced.<sup>22</sup> However, for patients who are already receiving appropriate antibiotics, no additional prophylaxis may be required. Patients known to be colonized with multiple resistant organisms or patients who have been hospitalized for some time before percutaneous endoscopic gastrostomy or jejunostomy insertion and who are likely to be colonized with resistant organisms should receive antibiotic prophylaxis appropriate to cover multiple resistant organisms. Local guidelines should be followed when choosing the antibiotic before percutaneous endoscopic gastrostomy or jejunostomy insertion. The choice of drug should be carefully considered in patients who are allergic to penicillin.

### Antibiotic Prophylaxis for Patients With Variceal Bleeding or Patients With Decompensated Liver Disease Who Develop Acute Gastrointestinal Bleeding

Prophylactic antibiotics in patients with variceal bleeding or in patients with decompensated liver disease who develop acute GI bleeding improves short-term survival and may be associated with a reduced risk of rebleeding.<sup>23</sup> It is recommended that patients receive antibiotics before endoscopy. The choice of antibiotics is determined by local guidelines, but ceftriaxone is frequently used.

### Antibiotic Prophylaxis for Patients With Neutropenia or Who Are Immunocompromised

Neutropenia ( $< 0.5 \times 10^9/L$ ) predisposes patients to sepsis after procedures such as endoscopy, but the level of risk is unclear.<sup>24</sup> Patients who are febrile should already be treated with empiric antibiotics according to local hematology guidelines. In afebrile patients, antibiotic prophylaxis should be offered for high-risk procedures such as sclerotherapy, esophageal dilation, or ERCP with duct obstruction. Gram-negative aerobic and, less frequently, anaerobic organisms are likely pathogens, and the choice of antibiotic should reflect local sensitivities. No data support the use of prophylactic antibiotics in patients who have a normal neutrophil count but who are nonetheless immunocompromised (e.g., organ transplants). Routine antibiotic prophylaxis is not recommended in patients with human immunodeficiency virus (HIV) infection.

Hyposmotic Agents, 105	Boston Bowel Preparation Scale, 106	Conclusion, 109
Adjunctive Therapy, 105		

## INTRODUCTION

Colorectal cancer (CRC) is the third leading cancer diagnosis and the third leading cause of cancer-related death in both men and women in the United States.<sup>1</sup> Colonoscopy is currently the gold standard in CRC prevention by allowing clinicians to detect and remove precancerous lesions. In addition, colonoscopy can be used for CRC surveillance and diagnostic evaluation of other positive CRC screening tests (e.g., fecal occult blood tests, fecal immunochemical tests, virtual colonography, etc.), as well other symptomatic complaints (e.g., diarrhea, hematochezia, etc.). The diagnostic accuracy and therapeutic safety of colonoscopy hinges on the quality of the colonic cleansing or preparation.

Unfortunately, current estimates suggest that up to 25% of bowel preparations are inadequate,<sup>2</sup> defined as the inability to achieve cecal intubation and effectively visualize the colonic mucosa.<sup>3</sup> Inadequate preparations can result in failed detection of precancerous or neoplastic lesions,<sup>4</sup> longer procedural times,<sup>5</sup> lower cecal intubation rates,<sup>6</sup> increased electrocautery risk,<sup>7</sup> and subjecting patients to multiple procedures due to the need for shorter intervals between endoscopic evaluations.<sup>2,6</sup>

There are several bowel-preparation formulations currently available on the market. Available formulations are assessed on their safety profile, efficacy, and patient tolerability. Studies have identified several independent patient-related predictors that increase the likelihood of an inadequate preparation: a previous inadequate colonoscopy, being non-English speaking, having Medicaid insurance, evidence of polypharmacy (particularly using medications that alter colon motility, i.e., tricyclic agents and opiates), obesity, advanced age, male sex, and comorbidities including diabetes mellitus, prior stroke, dementia, cirrhosis, prior gastrointestinal surgery, and Parkinson's disease.<sup>8-10</sup> Several physician- and procedure-related predictors that increase the likelihood of an inadequate preparation have also been identified: longer appointment wait times for colonoscopy, a procedural

indication of constipation, a later colonoscopy time, and inpatient status.<sup>8-10</sup> The ideal colonic preparation should be effective in evacuating the colon of all fecal material without resulting in any patient discomfort, fluid shifts, or electrolyte imbalances. Here we review the available colonoscopy preparations and discuss the optimal timing for taking the preparations. In addition, this review will provide up-to-date literature for clinicians to ensure patient safety and to potentially modify patient-, physician-, and procedure-related factors to optimize bowel preparation quality.

## AVAILABLE REGIMENS FOR COLONIC LAVAGE PRIOR TO COLONOSCOPY

Clinicians should be cognizant of cost, patient tolerability, and comorbid conditions when prescribing colon preparations. The available colon preparations are summarized later and in Table 9.1.

### Isosmotic Agents

Isosmotic agents are polyethylene glycol (PEG)-containing preparations that are osmotically balanced with non-fermentable electrolyte solutions, thus theoretically minimizing significant fluid and electrolyte shifts. These preparations cleanse the intestinal lumen through the cathartic effect that results from large-volume lavage.

PEG-electrolyte solutions (PEG-ELS) (GoLyteLy, Braintree Laboratories, Braintree, MA) is one of the most commonly prescribed colon preparations. There were no significant physiologic changes (e.g., weight, vital signs, serum electrolytes, blood chemistries, or blood counts) seen in clinical trials.<sup>11-13</sup> Thus, PEG-ELS is considered generally safe in patients with preexisting electrolyte disorders or those who cannot otherwise tolerate a significant sodium load (e.g., patients with advanced renal or hepatic impairment, or congestive heart failure).<sup>14</sup> Finally, PEG-ELS does not alter histologic features of colonic

**Abstract**

Although colonoscopy is recognized as the “gold standard” for current colon cancer screening testing, the quality of the exam is critically dependent on a high-level colon-cleansing preparation. This chapter will highlight the current pharmacologic and procedural advances in attaining a high-quality preparation as well as the scoring systems to assess adequacy of cleansing.

**TABLE 9.1 Summary of Available Bowel Preparations**

<b>Brand (Company)</b>	<b>Formulation</b>	<b>Volume (L)</b>	<b>FDA Approved?</b>	<b>Dosing Regimen</b>	<b>Caution</b>	<b>Hyper/Hypo/ Iso Osmotic</b>
Golytely (Braintree Laboratories)	PEG Sodium sulfate Sodium bicarbonate Sodium chloride Potassium chloride	4	Yes	Split dose (2 L day before and 2 L day of procedure) Single dose (4 L day before)	Least palatable	Iso
NuLYTELY Trilyte (Braintree Laboratories)	PEG Sodium bicarbonate Sodium chloride Potassium chloride	4	Yes	Split dose (2 L day before and 2 L day of procedure) Single dose (4 L day before)	More palatable (Sodium sulfate removed from formulation)	Iso
Moviprep (Salix Pharmaceuticals)	PEG-3350 Sodium sulfate Sodium chloride Ascorbic acid	2	Yes	Split dose (1 L day before and 1 L day of procedure) Single dose (2 L day before)	Potential to precipitate hemolysis in patients with G6PD	Iso
Miralax (Merck)	PEG-3350	238 g mixed with 64 oz of Gatorade to create a 2-L PEG-SD	No	Split dose (1 L day before and 1 L day of procedure) Single dose (2 L day before)	Fluid shifts and electrolyte derangements may occur  Caution in patients with hepatic/renal impairment or CHF	Hypo
Suprep (Braintree Laboratories)	PEG-3350 Sodium sulfate Potassium sulfate Magnesium sulfate	12 oz in 2.5 L of water	Yes	Split dose (6 oz OSS with 10 oz of water + 32 oz of water the day before and 6 oz OSS + 10 oz of water + 32 oz of water day of procedure)		Hyper
Suclear (Braintree Laboratories)	PEG-3550 Sodium sulfate Potassium sulfate Magnesium sulfate	6 oz OSS and 2 L PEG-ELS in 1.25 L of water	Yes	Split dose (6 oz OSS with 10 oz of water + 32 oz of water the day before and 2 L PEG-ELS day of procedure) Single dose (6 oz OSS with 10 oz of water + 16 oz of water followed by 2 L PEG-ELS + 16 oz of water 2 hours after OSS)		Hyper
Prepopik (Ferring Pharmaceuticals)	Sodium picosulfate Magnesium sulfate Anhydric citric acid	10 oz in 2 L of water	Yes	Split dose (5 oz Prepopik day before + 40 oz of clear liquid and 5 oz Prepopik + 24 oz of clear liquids day of procedure) Single dose (5 oz Prepopik + 24 oz clear liquids the afternoon or early evening day before procedure and 5 oz Prepopik + 24 oz of clear liquids 6 hours later)	Risk of magnesium toxicity Avoid in patients with nephrotic impairment	Hyper
Magnesium citrate (OTC)	Magnesium citrate	20–30 oz in 2 L of water	No	Split dose (1–1.5 10-oz bottles the day before and 1–1.5 10 oz bottles day of procedure)	Risk of magnesium toxicity Avoid in patients with nephrotic impairment	Hyper
Osmoprep (Salix Pharmaceuticals)	NaP	32 tablets in 2 L of water	Yes	Split dose (20 tablets day before and 12 tablets day of procedure)	Risk of calcium and phosphate nephropathy, particularly in those highly susceptible	Hyper

CHF, Congestive heart failure; FDA, Food and Drug Administration; PEG, polyethylene glycol; PEG-ELS, PEG-electrolyte solutions; PEG-SD, PEG + sports drink; OSS, oral sodium sulfate; OTC, over the counter.

mucosa and as a result can be used in patients suspected of having inflammatory bowel disease without affecting the diagnostic yield.<sup>15</sup>

One major pitfall of large-volume PEG-ELS is that nearly 15% of patients are unable to complete the preparation due to the large volume (resulting in abdominal fullness and cramping) and/or palatability (due to sulfate-associated taste).<sup>16</sup> To overcome these shortcomings, Food and Drug Administration (FDA)-approved reduced-volume PEG-ELS and sulfate-free PEG-ELS formulations were developed.

Low-volume PEG-ELS (Moviprep, Merck, Kenilworth, NJ), containing supplemental ascorbate and sodium sulfate, were formulated to provide a more tolerable preparation. Several studies have demonstrated similar efficacy with low-volume PEG-ELS compared with the standard 4-L PEG-ELS preparation.<sup>17–20</sup> The safety profile of low-volume PEG-ELS is comparable to that of standard large-volume PEG-ELS, with the exception of patients with glucose-6-phosphate dehydrogenase deficiency, as ascorbate may precipitate hemolysis in these patients.<sup>21</sup>

Sulfate-free PEG-ELS (SF-PEG-ELS) (NuLYTELY or Trilyte, Braintree Laboratories, Braintree, MA) was formulated to overcome the palatability issues of standard large-volume PEG-ELS by completely removing sodium sulfate, decreasing potassium concentration, and increasing chloride concentration.<sup>15</sup> This results in lower luminal sodium concentrations, thus SF-PEG-ELS formulations are solely dependent on its osmotic effects. Clinical data have demonstrated SF-PEG-ELS to be as efficacious and safe when compared with standard PEG-ELS.<sup>22</sup>

### Hyperosmotic Agents

Hyperosmotic agents draw water and electrolytes into the bowel lumen, resulting in fluid loss, peristalsis, and ultimately evacuation of the bowel. As a result, these small-volume preparations cause fluid shifts and can result in electrolyte derangements.

### Magnesium Citrate

Magnesium citrate is a commonly used agent that has an osmotic effect (as described earlier) and additionally stimulates the release of cholecystokinin, which results in intraluminal accumulation of fluid and electrolytes thought to promote colonic transit.<sup>23</sup> To date, there have been four randomized controlled trials evaluating the use of magnesium citrate for colonoscopy preparation, which included two trials that combined it with either PEG-ELS or sodium phosphate (NaP) solution.<sup>24–27</sup> Park et al (2010) evaluated the efficacy and tolerance of split-dose magnesium citrate and low-volume PEG for morning colonoscopy.<sup>24</sup> A total of 232 patients were randomized to receive 4-L PEG (group 1; day prior to procedure; n = 79), split-dose PEG (group 2; 2-L PEG day before the procedure followed by another 2-L PEG day of the procedure; n = 80), or magnesium citrate and PEG (group 3; 250 mL of magnesium citrate day before procedure followed by 2-L PEG day of the procedure; n = 73). They found that satisfactory bowel preparations were more frequently reported in group 3 when compared with group 1, and similar to that of group 2. In addition, they found that patients in group 3 were more willing to repeat the same preparation, if necessary, than those in group 1 (93% vs. 38%, p < 0.001) or group 2 (93% vs. 62%, p < 0.001), which led the authors to conclude that split-dose magnesium citrate low-volume PEG regimen was more efficient than the conventional 4-L PEG regimen, and equally efficient but preferable to the split-dose regimen for morning colonoscopy. Magnesium citrate does result in transient elevations in serum

magnesium levels; however, this has not been linked to any adverse outcomes in healthy persons.<sup>28</sup> It does undergo renal excretion, however, and thus should be avoided in patients with chronic kidney disease because of possible magnesium toxicity (resulting in bradycardia, hypotension, nausea, drowsiness, and even death).<sup>29,30</sup>

### Sodium Phosphate and Oral Sodium Sulfate

NaP (Osmoprep, Salix pharmaceuticals, Raleigh, NC) is a hyperosmotic solution that has recently lost favor due to the rare occurrence of calcium<sup>31</sup> and phosphate<sup>32</sup> nephropathy. Patient characteristics associated with a higher predilection toward phosphate nephropathy include compromised renal function, female gender, inadequate hydration during bowel preparation, hypertension treated with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, older age, or concomitant use of certain medications (diuretics or nonsteroidal antiinflammatory drugs).<sup>31</sup> Additionally, NaP can cause significant fluid shifts and electrolyte derangements, particularly in elderly patients or those with impaired gut motility, renal or hepatic impairment, or congestive heart failure.<sup>34</sup> Thus, the FDA has recently issued a black box warning for the tablet form of NaP.<sup>33</sup> It is not currently recommended for use in bowel preparation.<sup>34,35</sup>

Oral sodium sulfate (OSS) (Suprep or Suclear, Braintree Laboratories, Braintree, MA) is a hyperosmotic prep that is not associated with significant fluid shifts and electrolyte derangements, owing to the fact that sulfate is a poorly absorbed anion. Di Palma et al (2009) evaluated the efficacy of OSS as a bowel preparation for colonoscopy in adult patients.<sup>36</sup> This multicenter, single-blind, randomized, non-inferiority study compared the efficacy of OSS with PEG-ELS. The study, totaling 364 patients, randomized each patient to split-dose administration, in which the first portion was taken the evening before the colonoscopy and the second the morning of. They found that there was no difference between OSS and PEG-ELS, with successful preparations seen in 97.2% and 95.6%, respectively. Patients who received OSS did report slightly more gastrointestinal events (i.e., cramping, bloating, nausea and vomiting) than those that received PEG-ELS (p = 0.009). The investigators concluded that OSS is an effective alternative to PEG-ELS with a comparable safety profile. Another multicenter, single-blind, randomized, non-inferiority study by Rex et al (2010) randomized 136 adult patients undergoing outpatient colonoscopy to 4-L SF-PEG-ELS (given the night prior to colonoscopy) or OSS given in equally divided doses the evening prior to and morning of colonoscopy.<sup>37</sup> They found that a successful bowel preparation (98.4% vs. 89.6%; p = 0.04), in particular preparations rated as excellent (71.4% vs. 34.3%; p < 0.001), was achieved more frequently with OSS than SF-PEG-ELS. Given similar side effect profiles, the authors concluded that OSS was a safe alternative as a low-volume preparation for colonoscopy. A limitation of the study is the fact that SF-PEG-ELS was entirely administered the evening prior and not as a split dose.

### Sodium Picosulfate-Magnesium Citrate

The combination of sodium picosulfate-magnesium citrate (P/MC) (Prepopik, Ferring Pharmaceutical, Parsippany, NJ) was introduced to the United States market in 2012. P/MC has a dual mechanism as it combines the stimulant laxative properties of sodium picosulfate (which increases the frequency and force of peristalsis) and the hyperosmotic properties of magnesium

citrate.<sup>37</sup> Rex et al (2013) evaluated the efficacy of P/MC in a multicenter, assessor-blinded, randomized, non-inferiority study.<sup>38</sup> This phase 3 study randomized 601 patients to P/MC ( $n = 304$ ) or to day-before 2-L PEG-3350 and bisacodyl tablets ( $n = 297$ ). P/MC was superior to 2-L PEG-3350 in overall colon cleaning (84.2% vs. 74.4%) and in cleaning of the ascending (89.5% vs. 78.8%), transverse and descending colon (92.4% vs. 85.9%), and rectosigmoid (92.4% vs. 87.2%). Patients also reported higher tolerability (ease of consumption and taste) for P/MC than PEG-3350, leading the authors to conclude that the bowel-cleansing effects and tolerability of split-dose P/MC were superior to day-before preparation with 2-L PEG-3350 and bisacodyl tablets.

### Hyposmotic Agents

PEG-3350 powder (Miralax, Merck, Kenilworth, NJ) is an over-the-counter laxative (marketed for constipation) available as an 8.3-ounce bottle. It is often mixed with 64 ounces of Gatorade (PepsiCo, Chicago, IL) to formulate a 2-L PEG formulation (PEG-SD). In the clinical setting it is often combined with adjunctive medications such as bisacodyl.<sup>39</sup> Given conflicting data at present, the routine use of PEG-SD is not currently recommended.<sup>40</sup> Hjelkrem et al (2011) compared split-dose PEG-ELS to split-dose PEG-SD alone and in combination with pretreatment medications (bisacodyl or lubiprostone) to determine the efficacy and tolerability of PEG-SD for bowel preparation.<sup>40</sup> This prospective, blinded, randomized controlled trial totaling 403 patients randomly assigned patients to receive GoLyteLy (Braintree Laboratories, Braintree, MA), MiralAX (Merck, Kenilworth, NJ), Miralax with bisacodyl (10 mg), or Miralax with lubiprostone (24 µg). They found GoLyteLy was more effective at bowel cleansing than Miralax alone or in combination with lubiprostone or bisacodyl (average Ottawa bowel preparation scores for each group were 5.1, 6.9, 6.8 and 6.3, respectively;  $p < 0.001$ ). One study suggested that the use of PEG-SD results in lower adenoma detection rates (ADRs) compared with standard PEG-ELS due to differences in preparation quality.<sup>41</sup> However, several studies have demonstrated PEG-SD to be as efficacious as PEG-ELS with a comparable side effect profile.<sup>42–45</sup>

### Adjunctive Therapy

There have been a multitude of adjunctive agents that have been investigated with the hopes to enhance bowel preparation and/or visualization of the mucosa. Agents have included simethicone, flavored electrolyte solutions, prokinetics, spasmolytics, bisacodyl, senna, olive oil, and probiotics. None of these agents have consistently shown improved efficacy, safety, or increased patient tolerability of the bowel preparation; accordingly, they are not currently recommended for routine use as adjunct therapy.<sup>46</sup> However, prescribing physicians may find these agents useful in select circumstances. A summary of key studies evaluating adjunctive therapies for bowel preparation is presented here.

Wu et al (2011) conducted a meta-analysis evaluating the supplemental use of simethicone.<sup>47</sup> This review, totaling seven studies that compared the efficacy of simethicone with a purgative to a purgative alone, found that the overall efficacy of colon preparation was comparable (odds ratio [OR], 2.06; 95% confidence interval [CI], 0.56–7.53;  $p = 0.27$ ), despite a notable reduction in the presence of intraluminal bubbles (OR, 39.3; 95% CI, 11.4–135.9;  $p < 0.01$ ) in the simethicone cohort.

The use of prokinetic agents in combination use with purgative laxatives has not demonstrated adjunctive benefit. Metoclopramide

is a prokinetic agent that increases the amplitude of gastric contraction and peristalsis of the duodenum and jejunum without affecting colonic motility. The data indicate that prokinetic agents such as metoclopramide do not improve colonic cleaning but are conflicting as to their effect on patient tolerability,<sup>48</sup> thus it is not currently recommended as an adjunct to bowel preparation.<sup>49,50</sup> Senna and bisacodyl have been used as adjuncts to PEG-ELS, and although they have been demonstrated to improve tolerability,<sup>47</sup> they have not been as effective as standard colon preparation.<sup>49,51</sup>

A randomized trial by Repici et al (2012) comparing two low-volume PEG-ELS preparations (PEG-ELS citrate-simethicone with bisacodyl and PEG-ascorbate) did not demonstrate any difference in tolerability, safety, acceptability, and compliance.<sup>52</sup> Another study, which involved 107 patients, demonstrated that colon cleansing with 2-L PEG-ELS ascorbate was superior when compared to PEG-ELS with bisacodyl.<sup>53</sup> Pretreatment with olive oil has been shown to enhance both patient satisfaction and tolerability in addition to quality of right-side colonic cleansing; however, it did not impact the left colon when compared with 4-L PEG-ELS.<sup>54</sup> Finally, Lee et al (2010) evaluated the efficacy of a 2-week probiotic treatment (containing a mixture of *Bacillus subtilis* and *Streptococcus faecium*) or placebo with oral NaP in patients with and without constipation with the primary outcome measure being the quality of bowel cleansing.<sup>55</sup> They found that patients suffering from constipation were more likely to benefit from probiotic pretreatment compared with placebo (54.9% vs. 20.8%, respectively;  $p < 0.001$ ). However, patients with normal defecation did not benefit from probiotic pretreatment. Thus, they concluded that probiotic pretreatment may be considered in patients suffering from constipation, but did not appear to be of value in patients with normal defecation.

### SPLIT DOSING

A split-dose preparation is currently strongly recommended by the most recent multi-society guidelines on bowel preparation.<sup>51,56,57</sup> Since the publication of these guidelines, even more evidence supporting split-dose preparation has been made available, including two recent meta-analyses that reviewed all available randomized trials utilizing split-dose versus non-split-dose preparations.<sup>58,59</sup> The meta-analysis by Bucci et al (2014), which included 29 studies, evaluated the efficacy of split dose versus non-split dosing.<sup>58</sup> The overall results demonstrated that split-dose preparations were superior to non-split dosing. An adequate preparation was achieved in 85% and 63% of patients, respectively. Of note, this was independent of the laxative used. A secondary analysis, however, highlights an important consideration that likely explains the derived benefit of using split prep over a non-split prep: the concept of runway time. Runway time refers to the time elapsed between the last dose of purge and the beginning of the colonoscopy. The quality of colon preparation is inversely related to the duration of runway time owing to the arrival of liquid stool from the ileum, which produces a film in the proximal colon and impairs the detection of polyps, particularly flat lesions.<sup>58,59</sup> As such, the authors established that the optimal runway time after completion of the oral preparation is 3 hours. It is important to note that prep quality decreases after 4 to 5 hours and is negated after 5 hours, independent of the laxative used.<sup>58</sup>

A meta-analysis by Martel et al (2015), which included 47 trials (13,487 patients), also compared split-dose preparation to

day-before preparation.<sup>35</sup> Overall, split-dose preparations had a significantly better quality of colon cleansing when compared with day-before preparation, irrespective of the type of preparation used (OR, 2.51; 95% CI, 1.86–3.29). In addition, patients were more willing to repeat split-dose compared with day-before preparation (OR, 1.90; 95% CI, 1.05–3.46). Other studies have also found that patients were more willing to comply with a split-dose regimen.<sup>34,37</sup> Altawil et al (2014) surveyed 149 patients, scheduled for morning procedures, regarding their opinion about a split-dose regimen.<sup>37</sup> Among the 149 survey participants, 64% (95/149) of patients were willing to wake up early to complete the split prep; of these patients, the majority (68%) preferred an early-morning appointment, with 29% preferring late morning and only 3% preferring an afternoon appointment. In comparison, only 56% of primary care providers who were also surveyed on their opinion about the willingness of their patients to undergo morning bowel preparation thought their patients would be willing to undergo split dosing. Overall, these studies suggest that a split-dose preparation does not significantly impair patient compliance, despite the fact it often requires patients to wake early in the morning to complete the preparation. The only exception for performing non-split dosing is for same-day preparation on the day of colonoscopy, which has also demonstrated a similar efficacy.<sup>38</sup>

A 2017 randomized controlled trial totaling 690 patients undergoing colonoscopy for positive fecal immunochemical testing compared ADRs with use of split-dose preparation and day-before preparation.<sup>39</sup> Patients were randomized to receive either low-volume split-dose or day-before regimens. The proportion of patients with at least one adenoma detected was significantly higher in the split-dose group compared with the day-before group (53% [183/345] vs. 40.9% [141/345], respectively; relative risk [RR], 1.22; 95% CI, 1.03–1.46). Furthermore, the split-dose prep was associated with a significantly higher rate of detecting advanced adenomas compared with the day-before group (26.4% [91/345] vs. 20% [69/345], respectively [RR, 1.35; 95% CI, 1.06–1.73]). Per-polyp analysis found that the total number of adenomas and advanced adenomas per patient were significantly higher in the split-dose group compared with the day-before group (1.15 vs. 0.8,  $p < 0.001$ ; 0.36 vs. 0.22,  $p < 0.001$ ). Subgroup analysis evaluating the detection of sessile serrate lesions (7.8% vs. 4.1%,  $p = 0.053$ ) and right-sided adenomas (0.96% vs. 0.85%,  $p = 0.29$ ) favored the use of split-dose prep but failed to achieve statistical significance.

Overall, these studies support the current multi-society guidelines on bowel preparation that endorse the use of split dosing over day-before preparation for patients undergoing morning procedures.<sup>21,28</sup> For patients undergoing an afternoon procedure, same-day preparation is considered an acceptable alternative due to runway time. When using split dosing, patients and providers should time the second dose of the split preparation such that it begins 4 to 6 hours before procedure and is completed at least 2 hours before the scheduled time. As described earlier, split-dose preparation is associated with improved colon cleansing, increased patient compliance, and, most importantly, increased ADRs.

## DOCUMENTATION OF THE QUALITY OF BOWEL PREPARATION

There are several scoring systems available for evaluating the adequacy of bowel preparation. This section will outline and

discuss the Aronchick Scale, Ottawa Scale, and Boston Bowel Preparation Scale (BBPS). Table 9.2 summarizes the different scoring systems.

### Aronchick Scale

The Aronchick Scale rates the quality of preparation based on percentage of residual stool during initial inspection before any attempted washing or suctioning of the mucosa.<sup>39</sup> The scale ranges from 1 to 5 and assigns a whole, rather than segmental, score. Grading scores are: (1) excellent: small volume of clear liquid or greater than 95% mucosa seen; (2) good: large volume of clear liquid covering 5% to 25% of surface but greater than 90% of mucosa seen; (3) fair: some semisolid stool that could not be suctioned or washed away, but greater than 90% of mucosa seen; (4) poor: semisolid stool could not be suctioned or washed away and less than 90% of mucosa seen; (5) inadequate: repeat preparation needed. The Aronchick Scale has often been used as the gold standard for comparison of other bowel preparation scales because it assesses preparation quality on initial inspection, despite the fact that it has not been fully validated.<sup>35,38</sup>

### Ottawa Scale

The Ottawa Scale differs from the Aronchick Scale in that it assesses the quality of preparation in different segments (i.e., right colon, mid colon, and rectosigmoid). In addition, it provides an overall global score for colonic fluid. Total scores range from 0 (excellent) to 14 (very poor/inadequate). Segment scores range from 0 to 4: (0) excellent: mucosal detail clearly visible; (1) good: minimal turbid fluid in segment; (2) fair: necessary to suction liquid stool to adequately visualize colonic wall; (3) poor: necessary to wash and suction to obtain view; (4) inadequate: solid stool not cleared with washing and suctioning.<sup>31,41</sup> Global colonic fluid is rated as being either a 0, 1, or 2, which indicates a small, moderate, or large volume of fluid, respectively. The Ottawa Scale has demonstrated high global inter-rater reliability, as well as high reliability when applied to the individual colon segments.<sup>61</sup>

### Boston Bowel Preparation Scale

The BBPS assesses bowel preparation after the mucosa has been cleaned to the best of the endoscopist's ability. The scoring system is applied to each of the three areas of the colon: right side (including cecum and ascending colon), transverse section (including hepatic and splenic flexures), and left side of the colon (including the descending colon, sigmoid colon, and rectum). Point assignments are 0 to 3 for each segment, with total scores ranging from 0 to 9. The scoring system for each segment is as follows: (0) unprepared colon segment with mucosa not seen because of solid stool that cannot be cleared; (1) portion of mucosa of the colon segment seen, but other areas of the colon segment are not well seen because of straining, residual stool and/or opaque liquid; (2) minor amount of residual staining, small fragments of stool and/or opaque liquid, but mucosa of colon segment is seen well; (3) entire mucosa of colon segment seen well, with no residual staining, small fragments of stool, or opaque liquid. If the procedure is aborted due to inadequate preparation, any non-visualized segments are assigned a score of 0.

In a comprehensive validation study, the BBPS demonstrated near-perfect inter-rater reliability and substantial intra-rater reliability.<sup>42</sup> BBPS scores also correlated with polyp detection rates, as scores of 5 or over had a higher polyp detection rate than scores lower than 5 (40% vs. 24%, respectively;  $p < 0.02$ ).<sup>43</sup>

**TABLE 9.2 Summary of Bowel-Preparation Scoring Scales**

<b>Aronchick Scale</b>		
<b>Score</b>	<b>Rating</b>	<b>Description</b>
1	Excellent	Small volume of clear liquid or > 95% mucosa seen
2	Good	Large volume of clear liquid covering 5%–25% of surface but > 90% of mucosa seen
3	Fair	Some semisolid stool that could not be suctioned or washed away, but > 90% of mucosa seen
4	Poor	Semisolid stool could not be suctioned or washed away and < 90% of mucosa seen
5	Inadequate	Inadequate; repeat preparation needed

<b>Ottawa Scale</b>		
<b>Segment Score*</b>		
<b>Score</b>	<b>Rating</b>	<b>Description</b>
0	Excellent	Mucosal detail clearly visible
1	Good	Minimal turbid fluid in segment
2	Fair	Necessary to suction liquid stool to adequately visualize colonic wall
3	Poor	Necessary to wash and suction to obtain view
4	Inadequate	Solid stool not cleared with washing and suctioning

<b>Global Score for Retained Fluid</b>		
<b>Score</b>	<b>Description</b>	<b>Rating</b>
0	Small	None
1	Moderate	Very little
2	Large volume	Significant amount

\*Segment scores are applied to each of the three colonic segments: right colon, mid colon, and rectosigmoid.

Total scores include the sum of the three segments scores plus the global fluid score. Total scores range from 0 (excellent) to 14 (very poor/inadequate). Scores for the Ottawa and Aronchick Scale are based on assessments performed prior to colonoscopic suction and lavage.

<b>Boston Bowel Preparation Scale</b>		
<b>Score</b>	<b>Description</b>	<b>Rating</b>
0	Unprepared colon segment with mucosa not seen because of solid stool that cannot be cleared	Unprepared
1	Portion of mucosa of the colon segment seen, but other areas of the colon segment are not well seen because of straining, residual stool, and/or opaque liquid	Partially prepared
2	Minor amount of residual staining, small fragments of stool, and/or opaque liquid, but mucosa of colon segment is seen well	Prepared
3	Entire mucosa of colon segment seen well, with no residual staining, small fragments of stool, or opaque liquid	Well prepared

Score applied to three segments:

1. Right side (including cecum and ascending colon)
2. Transverse section (including hepatic and splenic flexures)
3. Left side of the colon (including the descending colon, sigmoid colon, and rectum)

Point assignments are 0–3 for each segment, with total scores ranging from 0–9.

If the procedure is aborted due to inadequate preparation, any non-visualized segments are assigned a score of 0.

Scores are based on assessments performed after completion of colonoscopic suction and lavage.

Additionally, a segment score of 2 or 3 was associated with improved polyp detection for both right- (OR, 1.60; 95% CI, 1.01–2.55) and left-sided polyps (OR, 2.58; 95% CI, 1.34–4.98) compared with a segment score of 0 or 1.<sup>21</sup>

### Comparison and Recommendations

According to the United States Multi-Society Task Force (USMSTF), quality indicators for colonoscopy include a primary goal to achieve a bowel preparation adequate to detect a lesion of greater than 5 mm.<sup>22</sup> In addition, the USMSTF also recommends that endoscopists achieve a minimum of 85% adequate bowel preparation rate in their practice.<sup>23</sup> If the threshold is not met, the process of preparation, patient education, navigation tools, and medication selection all warrant closer review in order to better optimize outcome.<sup>23</sup> The European Society of Gastrointestinal Endoscopy guidelines on adequate bowel preparation propose that at least 90% of screening examinations be rated as having an “adequate” or better bowel cleansing.<sup>24</sup>

A systematic review and meta-analysis totaling 11 studies by Clark et al (2014) investigated the impact of bowel preparation quality on the ADRs using the Aronchick Scale, comparing high-quality (excellent/good), intermediate-quality (fair), and low-quality (poor/insufficient) bowel preparation.<sup>24</sup> Overall, ADRs were significantly higher for both the high- and intermediate-quality preparation groups compared with the poor-quality group (OR, 1.41; 95% CI, 1.21–1.64 and OR, 1.39; 95% CI, 1.08–1.79, respectively). However, there was no significant difference in ADR between the high- and intermediate-quality groups (OR, 0.94; 95% CI, 0.80–1.10). A 2016 meta-analysis by Sulz et al investigated the effects of bowel preparation on ADR, advanced adenomas, and CRC.<sup>25</sup> They found that detection of early adenomas was significantly reduced with inadequate (poor or insufficient) preparations compared with adequate (excellent, good, or fair) preparations (OR, 0.53; 95% CI, 0.46–0.62). This was also true for advanced adenomas (OR, 0.74; 95% CI, 0.62–0.87). Thus, it appears that an inadequate bowel preparation affects the detection

of early colonic lesions more so than for advanced lesions, but both are reduced.

A 2016 prospective observational study by Clark et al sought to provide an objective definition of an adequate preparation using the BBPS.<sup>64</sup> Data were collected from 438 male patients undergoing screening and surveillance colonoscopies who then underwent a repeat colonoscopy within 60 days by a different blinded endoscopist. BBPS was used to quantify adequacy of bowel preparation. They found that a BBPS segment score of 2 or 3 for all colon segments was sufficient for detection of adenomas of 5 mm or greater and that patients meeting these criteria should return for screening or surveillance colonoscopy at standard guideline-recommended intervals, and these colonic preparations were thus considered adequate. Conversely, segments with a BBPS score of 1 had a significantly higher rate of missed adenomas of 5 mm or greater, when compared with segments with scores of 2 or 3.

Despite an adequate ADR for both intermediate- and high-quality bowel preparation, evidence from 2016 suggests that only high-quality bowel preparation is adequate for the detection of sessile serrated adenomas/polyps (SSPs).<sup>67</sup> A prospective trial comparing the SSP detection rate among 749 patients undergoing screening and surveillance colonoscopies in which the endoscopists graded the quality of bowel preparation using both the Aronchick Scale and the BBPS was performed.<sup>67</sup> When using the Aronchick Scale, detection of SSPs was significantly lower in patients with intermediate-quality preparation (4.6%) compared with high-quality preparation (12.0%; OR, 0.37; 95% CI, 0.15–0.87). This finding also held true for the BBPS, where significantly fewer SSPs were detected in patients with a BBPS of less than 7 compared with a score of 7 to 9 (4.7% vs. 12.6%; OR, 0.36; 95% CI, 0.19–0.67).

Currently, the multi-society guidelines on bowel preparation for CRC screening strongly recommend documentation of the adequacy of the bowel preparation, ideally assessed after all appropriate efforts to clear residual debris have been completed.<sup>23,28</sup> As a result, the guidelines do not recommend the use of the Aronchick Scale or Ottawa Scale because these scales score retained fluid.<sup>23</sup> Based on the currently available evidence, if employing the BBPS to assess colon cleansing, any score less than 5 warrants a repeat colonoscopy in less than 1 year, whereas those with total scores of 7 or higher, or if all segment scores are 2 or greater, can follow appropriate guideline-recommended screening intervals.

## DIET DURING BOWEL CLEANSING

Traditionally, patients are instructed to ingest only a clear liquid diet (e.g., transparent liquids) the day prior to colonoscopy to decrease the likelihood of residual food contents. A 2016 meta-analysis, however, evaluating nine studies totaling 1686 patients evaluated the outcomes of patients undergoing colonoscopy who consumed a clear liquid diet versus a low-residue diet the day prior to colonoscopy.<sup>68</sup> They found that patients consuming a low-residue diet demonstrated significantly higher odds of tolerability (OR, 1.92; 95% CI, 1.36–2.70;  $p < 0.01$ ) and willingness to repeat preparation (OR, 1.86; 95% CI, 1.34–2.59;  $p < 0.01$ ) when compared with those who underwent a clear liquid diet. In addition, they found no difference in adequate bowel preparations (OR, 1.21; 95% CI, 0.64–2.28;  $p = 0.58$ ) or adverse effects (OR, 0.88; 95% CI, 0.58–1.35;  $p = 0.57$ ). It should be noted, however, that the diet regimens in these trials were variable

(heterogeneity:  $p = 0.008$ ,  $I^2 = 62\%$ ). Regimens included a regular diet until 6 PM, regular breakfast, low-residue breakfast, lunch and snack, a soft diet, and a semi-liquid diet. Thus, consensus guidelines include full liquids until the evening on the day prior to colonoscopy and consideration of a low-residue diet for part or all of the day prior to colonoscopy, particularly in patients without identifiable pre-procedural risks for inadequate bowel preparation (e.g., constipation).<sup>28</sup>

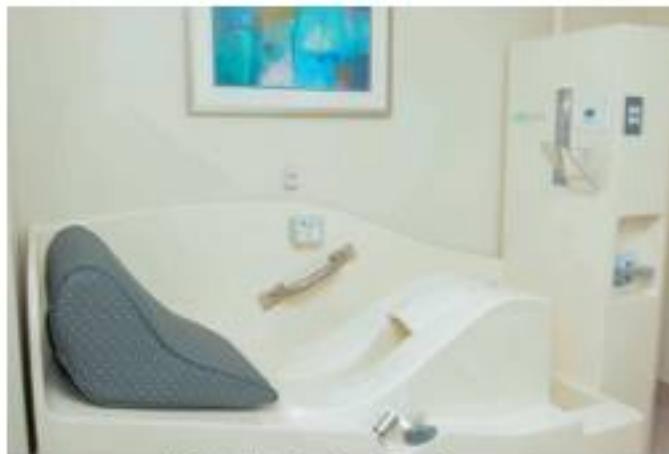

## FUTURE DIRECTION OF BOWEL PREPARATION

### Colon Hydrotherapy

The Angel of Water device (Lifestream, Austin, TX), referred to as the Prep System, was initially developed by institutes promoting "well-being" via a method of comfortable colonic hydrotherapy to achieve colon cleansing. A 2016 prospective, non-inferiority study compared a standard PEG protocol with bowel cleansing by low-pressure water infusion into the colon (Prep System, Lifestream, Austin, TX). Patients were randomly assigned to either a split-dose 2 L + 2 L PEG or the Prep System, after 5 days on a low-residue diet.<sup>69</sup> Prep System cleansing consisted of infusion of 35-L water ( $\times 2$ ) at 37°C into the rectum over a 1-hour period. The quality of bowel cleansing was assessed using the BBPS by a colonoscopist blinded to the preparation. Groups were comparable for age, sex, and colonoscopy indication.

The total median BBPS (7 in both groups) and segmental scores did not differ between groups. Mean duration of colonoscopy, blood electrolytes after bowel cleansing, and patient satisfaction (89% in the patients who underwent prep using the Prep System vs. 76% in the PEG cohort) did not differ between the two groups. Adverse events, mainly nausea, were more frequent in the PEG group ( $p = 0.03$ ). In the setting of this study, the Prep System appeared as effective as the split-dose prep using PEG for bowel cleansing before colonoscopy with similar, if not better, patient tolerance.

The system is currently licensed by HyGleaCare (Austin, TX), with over 4600 patients successfully having undergone this procedure to date with excellent success and acceptability by patients.<sup>70</sup> HyGleaCare Prep provides a FDA-cleared colon lavage system to replace the traditional oral prep. The patient sits comfortably on a padded recliner while a colon purge with low-pressure warm water is delivered comfortably via a small soft rectal tube (Fig. 9.1). The colonic effluent washes out the

**FIG 9.1** HyGleaCare Prep System.

rectum, and colonic cleansing is achieved typically within 45 minutes. The HyGleacare Prep is private, uses low-pressure flow of warm water, is odorless, and effective. The patient undergoes their scheduled colonoscopy immediately after undergoing their prep, which offers a novel alternative to the traditional preparation by overcoming several barriers to effective colonoscopy preparation (e.g., intolerance of large-volume oral purgatives).

## CONCLUSION

Colonoscopy is the mainstay in CRC diagnosis and prevention; however, the effectiveness of colonoscopy hinges on an adequate colon preparation. Ineffective bowel cleaning results in missed lesions, increased cost, and repeated procedures. National guidelines in the United States have emphasized the hurdles faced with bowel preparation for colonoscopy and the consequences of inadequate colon preparation. These challenges include intolerance of the preparation and inadequate preparation quality, which then impacts important benchmarks for quality, including ADRs, compliance with appropriate surveillance intervals, and in achieving the new threshold benchmark for adequate preparation (now set at 85%). There are several scoring systems available that can be used to calculate whether a prep is adequate or inadequate. The quality of the bowel preparation should be determined after the endoscopist has thoroughly attempted to cleanse the bowel. The choice of bowel preparation for colonoscopy should be individualized to the patient based on a number of factors including cost, tolerability, and patient comorbidities. Any method that improves the acceptability and effectiveness of the colon preparation prior to colonoscopy is a key and critical step toward the ultimate goal: achieving a quality colonoscopy!

Breach of Duty, 111	<b>Informed Consent, 112</b>	Best Practice for Managing Complications and Error, 114
	<b>Disclosure of Protected Health Information, 113</b>	

Endoscopic evaluation has become an indispensable and powerful tool for prevention, diagnosis, and therapy for digestive disorders. Performance of endoscopic procedures is not without risk, however. In the event of a bad outcome, physicians may face legal liability. It is therefore important that gastroenterologists understand the types of legal risk they may face and best practices for managing those risks.

This chapter briefly addresses legal aspects of gastrointestinal endoscopy. Part I of this chapter describes the types of malpractice lawsuits faced by gastroenterologists. Part II describes the anatomy of a malpractice suit, including the role of adherence to the applicable standard of care. Part III describes the basic elements and importance of obtaining and documenting informed consent. Part IV briefly summarizes legal obligations regarding protected health information. Finally, part V concludes with a discussion of risk management approaches, including good documentation practices, use of clinical practice guidelines (CPGs), and best practices for managing complications and errors once they have occurred.

## TYPES OF LAWSUITS FACED BY GASTROENTEROLOGISTS

Malpractice lawsuits are a fact of practice for physicians in the United States. Beginning in the 1990s, several large studies, including the landmark Harvard Medical Malpractice Study, revealed surprising levels of medical errors and malpractice suits and provided an important impetus for the safety movement.<sup>1–5</sup>

More recently, a published study of claims data from 1991 through 2005 for all physicians covered by a large, national professional liability insurer revealed that each year 7.4% of physicians had a malpractice claim, with 1.6% having a claim

leading to payment.<sup>4</sup> The study identified a large degree of variation by specialty in physicians' risk of facing a malpractice lawsuit. Gastroenterologists during the study period faced a higher degree of malpractice risk than US physicians overall, with over 10% of gastroenterologists facing a malpractice claim annually.<sup>4</sup> Because gastroenterology involves the performance of invasive procedures, such as colonoscopies, this slightly elevated malpractice risk is not surprising.

To avoid potential lawsuits, it is important for gastroenterologists practicing in the United States to be familiar with the types of malpractice claims gastroenterologists most often face. One common type of malpractice claim gastroenterologists face is a claim of missed or delayed diagnosis. These claims often stem from a delayed diagnosis of colorectal cancer (CRC) due to missteps such as failure to conduct an initial CRC screening with the appropriate level of care, failure to notify patients of abnormal test results, and failure to ensure that patients complete follow-up appointments.<sup>5</sup> Other types of malpractice claims gastroenterologists face include claims related to improper performance of a procedure (e.g., a perforated bowel resulting from poor colonoscopy technique) or failure to monitor a patient's case. In addition to claims arising from medical error, malpractice liability may also result from "nonmedical" conduct, such as failure to obtain informed consent or breach of patient confidentiality and privacy protections.

Data on the relative frequency of different types of malpractice claims against gastroenterologists is limited. However, a review of gastroenterology claims data compiled by the Physician Insurers Association of America (PIAA) from 1985 through 2005 revealed that the most common reasons gastroenterologists face malpractice lawsuits are "error in diagnosis" (28% of claims), "improper performance" of a procedure (25% of claims), "failure to supervise or monitor case" (9% of claims), and performance of a procedure "when not indicated or contraindicated" (2.3% of claims).<sup>6</sup> There was no "medical misadventure" identified in 19% of claims.<sup>6</sup>

---

This chapter is written for educational purposes, and should not be construed to provide specific legal advice; for that the reader will need to consult his/her own health care attorney.

**Abstract**

This chapter concisely addresses legal aspects of gastrointestinal endoscopy. Topics discussed include legal epidemiology, basic concepts, and a description of the tort of negligence, which is the most common type of malpractice lawsuit faced by gastroenterologists. The elements of DUTY, BREACH, CAUSATION, and HARM that must be proven for the plaintiff to prevail are explained. Other topics reviewed include the role of adherence to the applicable standard of care; the use of clinical guidelines, quality measures, and expert witnesses to assess standard of care; and the importance of obtaining and documenting informed consent. The legal obligations regarding protected health information are summarized. The chapter concludes with a discussion of risk management approaches, including good documentation practices, use of clinical practice guidelines (CPGs), and best practices for managing complications and errors once they have occurred.

## LEGAL PRINCIPLES IN MEDICAL PRACTICE

Medical malpractice actions are typically based on the legal theory of negligence. A claim of negligence requires the plaintiff's attorney to prove four elements:

1. Duty: The physician owed an obligation of care to the plaintiff;
2. Breach of Duty: The physician violated that duty by practice below the applicable standard of care;
3. Causation: The physician's substandard practice caused harm to that individual; and
4. Damages: The plaintiff suffered cognizable and compensable harm.

### Duty

To prove the element of duty, it generally suffices to establish the existence of a physician-patient relationship. Although a physician has no legal duty to accept a person as a patient or to provide care to a person with whom the physician does not have a physician-patient relationship, once the physician establishes a physician-patient relationship with an individual, the physician has a duty to provide competent care to that person and could be held liable for failure to do so.

It is generally evident when such duty has been established. For example, a physician-patient relationship may be established by the patient entering the hospital or clinic and the physician accepting to or beginning to treat the patient. The duty of care may also be established in less obvious situations, however, such as when advising an emergency room physician about a patient while on call or providing a "curbside consult" to a patient while not on call.

As less formal methods of medical communication, such as medical web platforms or emails that allow patients to interact with physicians, become more prevalent, it is important for physicians to remain cognizant of the potential for such venues to lead to the establishment of a physician-patient relationship and the corresponding duty of care.

### Breach of Duty

To prove the element of breach, the plaintiff must show that the physician did not provide the level of care that a reasonable and prudent member of the medical profession would undertake under the same or similar circumstances.<sup>7,8</sup> Breach may be established by showing that the treatment itself was substandard or that the physician failed to obtain informed consent to the procedure from the patient. With respect to substandard treatment, whether a physician has breached his or her duty to the patient and provided inadequate care is determined in reference to the standard of care that the physician was expected to provide. The standard of care is based on prevailing practice and may be established by the testimony of an expert in the field as to whether the physician's care was adequate or, with increasing frequency, reference to CPGs or quality measures. Importantly, it is not the negative result that determines whether the physician breached his or her duty to the patient, but whether the physician acted with the degree of skill and care of a reasonable physician in the circumstances. One must distinguish a "bad outcome" from negligence.

The current standard of care and whether the physician's conduct fell short of this standard has traditionally been established through expert witness testimony, but courts are increasingly relying on respected national guidelines as well. CPGs are

treatment standards developed by practitioners (typically medical associations) and are informed by a systematic review of evidence and assessment of the benefits and harms of alternative care options.<sup>9</sup> While a court will regard such guidelines as relevant evidence, it generally will not allow them, standing alone, to establish the standard of care in any given situation.<sup>10</sup> Nevertheless, CPGs and quality measures may be cited by experts and become important determinants of the standard of care.

While in many cases breach must be established by reference to expert testimony or medical guidelines, in certain cases the breach falls within the "common knowledge"<sup>11</sup> or "obvious occurrence"<sup>12</sup> exception, wherein the wrong committed is within the realm of a layperson's comprehension (e.g., a sponge retained in the abdomen at surgery, or amputation of the wrong limb). Expert witnesses are also unnecessary under a similar but technically separate doctrine called *res ipsa loquitur* (the thing speaks for itself), a legal term applying to a narrow category of malpractice cases in which the jury may infer negligence from the mere fact of an accident's occurrence.<sup>13</sup> Whereas some jurisdictions openly disfavor application of *res ipsa loquitur* in medical malpractice cases,<sup>14</sup> other jurisdictions apply it in common knowledge or obvious occurrence cases.

### Causation

The third element, causation, may be established by showing that the physician's substandard medical care directly led to the harm experienced by the plaintiff. Causation is frequently the most complicated and difficult element for plaintiffs to prove in medical malpractice cases. Because patients commonly have preexisting conditions, it is often difficult to determine whether the physician's substandard practice "caused" the patient's bad outcome or whether the patient's harm would have happened anyway.

Although the causation analysis varies from state to state, a 2014 case involving a gastroenterologist in Pennsylvania provides a good illustration of how courts have handled complex causation analysis in malpractice cases.<sup>15</sup> The plaintiff in this case suffered from chronic constipation for which her gastroenterologist prescribed Visicol. Visicol is approved for cleansing the colon for a colonoscopy; use of Visicol for long-term treatment of chronic constipation was an off-label use. The plaintiff was on Visicol for five years before her nephrologist took her off the medication after diagnosing her with permanent, progressive kidney disease. At trial, the plaintiff presented evidence that her kidney failure was caused by long-term ingestion of Visicol as prescribed by her gastroenterologist. The defendant gastroenterologist responded by raising the patient's history of bulimia, hypertension, and nonsteroidal antiinflammatory drug (NSAID) use as alternative explanations for the kidney disease.

Following the trial, a jury determined that the gastroenterologist was negligent, but denied recovery to the plaintiff, finding that she had failed to prove causation. As interpreted by the lower court, causation required a showing that *but for* the Visicol prescription, the plaintiff would not have experienced the injury of progressive kidney disease. Given the plaintiff's preexisting conditions, this could not be established. The case did not end there, however. The patient appealed the case, and the appellate court remanded the case for a new trial with an instruction to apply an alternative theory of causation, the increased risk theory. Under the increased risk theory, a plaintiff may prove causation based on a showing that the defendant's conduct increased the risk that the harm sustained by the plaintiff would occur. Thus,

even though Visicol may not have caused the plaintiff's kidney disease, the plaintiff could recover by demonstrating that chronic use of Visicol caused an increased risk of developing kidney disease.

### Damages

Finally, plaintiffs must prove the fourth element, damages, by showing that they experienced some form of compensable harm. Once the plaintiff has established each of the elements of the malpractice suit, the defendant physician or medical practice is required to pay all damages suffered by the plaintiff, even if surprisingly great in scope.

The amount of damages a plaintiff can recover explains why some types of malpractice cases are brought with significantly greater frequency than others. For example, missed or delayed diagnosis of CRC is the most frequent and serious lawsuit against gastroenterologists.<sup>6,10</sup> CRC is a serious illness and may therefore result in a large damages award. Similarly, a young patient with inflammatory bowel disease who becomes disabled after a negligent event may have a large claim for medical expenses and future lost income. The potential for a large settlement or judgment is enough to justify to the plaintiff's attorney the expense of bringing a malpractice suit.

### Apportioning Damages Among Multiple Defendants

In many malpractice cases, the patient sues multiple providers who were involved in his or her care. This creates complex questions about how damages in the case will be apportioned among the defendants. One question that arises is how responsibility for payment of damages is handled where one of the defendants is either unable to or does not pay. There are two main ways states handle this issue, though many states have modified these models in some respects. Under a "joint and several liability" system, each defendant is individually liable for all the damages in the case. If all defendants are able to pay, the plaintiff recovers the damages from all the defendants. If one or more of the defendants is unable to pay, the other defendants are responsible for paying all the damages. Conversely, under a "several liability" system, defendants are responsible for their proportionate share of the damages, and if one of the defendants does not pay, the other defendants are not responsible for covering that share of the damages.

As of 2014, the National Conference of State Legislatures reports that about half of the states allow for joint and several liability and half have a several liability system.<sup>17</sup> This is an oversimplification of the landscape, however, as most states have modified these systems to some extent. For example, some states have hybrid liability rules, where joint and several liability applies to some portion of damages (e.g., joint and several liability for economic damages and several liability for noneconomic damages). In some states, whether joint and several liability or several liability applies depends on some aspect of the case, such as the defendant's percentage fault in the case.

### Vicarious Liability

Another critical issue that arises in many malpractice cases is the question of "vicarious liability." Vicarious liability is a legal concept that extends liability for a wrongdoing beyond the original wrongdoer to persons who have not directly committed a wrong, but on whose behalf the wrongdoers acted. The primary practical importance of this concept is that it provides the plaintiff with additional financially responsible defendants who likely have

greater resources than the original defendant. For example, in the context of medical malpractice lawsuits, a hospital could be held directly liable for its own negligence (e.g., due to poorly maintained equipment) and could also be held vicariously liable for the negligence of its employees (e.g., if a nurse administered the wrong medication).

For the practicing physician, the implication of vicarious liability is that physicians can be held legally liable not only for their own actions but also for the actions of others whom they are responsible for supervising. This holds even if the gastroenterologist had neither personally committed nor even was aware of the wrongful act. Thus, if a nurse involved in an endoscopy procedure failed to use sterile technique or appropriately monitor the patient, causing the patient harm, the gastroenterologist performing the procedure could be vicariously liable for the injuries caused by the nurse. In another example, if the physician's medical assistant fails to provide notification of an urgent postprocedure call regarding a developing complication, or gives incorrect postprocedure advice, the supervising gastroenterologist could be held liable, despite being unaware of the call or advice.

### Defenses

When faced with a medical malpractice claim, there are certain "affirmative defenses" available to physicians. One defense that may be raised is a statute of limitations defense. If the plaintiff does not bring a malpractice claim until after the time period specified in the relevant state's statute of limitations has lapsed, then the case is barred. The statute of limitation varies by state, but typically is in the realm of two to three years.

Another affirmative defense that may be raised in a malpractice case is "contributory negligence" of the patient. This is an important defense in the medical malpractice context, because plaintiffs are often at least partially responsible for their own injuries (e.g., if the patient skipped follow-up appointments or failed to take medications as recommended). In the past, contributory negligence was a complete defense, and plaintiffs could not recover anything if they were partially responsible for their own injury. This is not the current state of the law, however, and contributory negligence will typically only serve as a partial defense that may reduce damages. Different states take different approaches to handling contributory negligence. In states that have a "pure" comparative negligence system, the plaintiff is entitled to the percentage of the damages for which the defendant is liable. Other states have modified this comparative negligence system by, for example, only allowing the plaintiff to recover damages if the defendant was at least 50% responsible for the damages.

## INFORMED CONSENT

Failure to obtain effective informed consent may provide a basis for establishing breach of duty in a medical malpractice case. A physician violates his or her duty to obtain a patient's informed consent if he or she fails to disclose facts necessary for the patient to form intelligent consent to the proposed treatment.<sup>18</sup>

It is critical to recognize that the duty to obtain informed consent requires more than the patient's pro forma consent to treatment. For consent to be valid, the patient must voluntarily consent to treatment after receiving information on, and understanding, the material risks and benefits of the proposed treatment and available alternative treatments.<sup>19</sup> Thus, while some

malpractice suits may involve a complete failure to obtain a patient's consent to treatment, most malpractice suits with an informed consent element involve allegations that the physician did not disclose sufficient information to allow the patient to make a truly informed decision when giving consent.<sup>20</sup>

In determining whether the physician satisfied his duty to inform the patient of material risks and alternative treatments, courts apply one of two standards. In some states, courts apply a "reasonable person" standard, under which physicians are required to disclose that information which a reasonable person would find important in deciding about a treatment. Other states have adopted a "prudent physician" standard. Under this approach, physicians must disclose that information which a reasonable physician in similar circumstances would disclose.

It is also important to keep in mind that informed consent may be withdrawn, potentially subjecting the physician to liability for any treatment administered after consent was withdrawn.<sup>21–24</sup> The question of liability based on withdrawal of consent is handled differently from state to state. In some states, for example, providers are liable only if the patient's withdrawal of consent satisfies a two-part test. First, the patient's withdrawal must have been done in a manner as to "leave no room for doubt in the minds of reasonable men that in view of all the circumstances consent was actually withdrawn."<sup>25</sup> Second, at the time the patient withdrew consent, it must have been medically feasible to desist in the treatment without the cessation being detrimental to the patient's health.<sup>25</sup>

There are a number of steps gastroenterologists may take to reduce the risk of liability for failure to obtain informed consent. These steps are particularly relevant for open access or direct access procedures. As an initial step, gastroenterologists should adopt an intake process where the patient is mailed or verbally given information about the relevant procedure (e.g., CRC screening). This mailing or discussion should include a description of the procedure, the purpose of the procedure, the risks and benefits of the procedure, and alternative treatments or diagnostic options. The office should document the patient's receipt of this information and whether the patient had any questions or concerns about the procedure. For any patients who appear uncertain or have many questions, the office should schedule a preprocedure consultation appointment with the physician. Finally, on the day of the procedure, the physician should obtain the patient's documented consent to the procedure. Where thorough information is provided to the patient through a process similar to that described here, the physician can fulfill his or her legal obligation to obtain informed consent by summarizing the information at the time he or she obtains the patient's consent.

## DISCLOSURE OF PROTECTED HEALTH INFORMATION

As the practice of medicine shifts to incorporate information technology, there have been many improvements in physicians' ability to document, store, and exchange patient data, communicate between physicians and with patients, monitor patients more effectively, and reduce administrative inefficiencies. Alongside these improvements, a host of legal risks for physicians have emerged, such as new standards of care arising from increased access to patient records, liability for failure to respond adequately and rapidly to questions sent over email, and issues relating to the focus of this section, the disclosure of protected health information.

Patients have a legal right to, and in many cases are dependent on, the confidentiality of their medical records. Disclosure of such protected health information can lead to liability for the physician, hospital, or storing facility for the data. The United States has a network of laws and standards relating to the protection of patient health information.

Two important rules to keep in mind are the Health Insurance Portability and Accountability Act of 1996 (HIPAA) Privacy Rule and the HIPAA Security Rule. The former establishes national standards to protect the privacy and limit use and disclosure of all individually identifiable health information relating to the individual's past, present, or future physical or mental health condition, the provision of health care to that individual, or the payment for such care where the individual is identified. The HIPAA Security Rule deals with electronic protected health information and requires the implementation of administrative, physical, and technical safeguards to protect the information covered in the HIPAA Privacy Rule. The penalty for breaching the rights of patients under these rules was increased in 2010 with the introduction of the Health Information Technology for Economic and Clinical Health (HITECH) Act from a maximum of \$250,000 to over \$1.5 million.

Unless a statutory exception applies, physicians should ensure that they do not disclose, intentionally or through a failure to include sufficient safety mechanisms, identifying patient information, unless they have consent for such disclosure. When communicating with patients over email, physicians should ensure that all email communication with patients is compliant with HIPAA, transferred over secure networks, and with sufficient disclaimers or precautions about the timeliness of email communication and potential outsider access.

## RISK MANAGEMENT APPROACHES

While there is no way to entirely insulate a medical practice from malpractice risk, there are a number of steps that can be taken to reduce risk. Many gastroenterology practices have implemented risk management programs designed to reduce legal risk through implementation of proactive strategies.

Elements of a risk management program in gastroenterology may include<sup>26–29</sup>:

1. A codified peer review process, which may include reviews of complications and sentinel events;
2. Unit reviews, which should include, among other things, monitoring of infection control steps for colonoscopy and other procedures, and assessment of the adequacy of appointment reminder systems and results notification;
3. Use of CPGs and documented practice plans (e.g., a written policy for responding to postprocedure patient concerns or complications);
4. Training of office staff on malpractice risks, risk mitigation techniques, and effective communication with patients<sup>30,31</sup>;
5. Documentation of all aspects of a patient's care (such as informed consent, patient experience during procedures, and instructions given to patients)<sup>30,32</sup>; and
6. Coverage by adequate malpractice insurance.

## Good Documentation Practices

As described previously, one aspect of an effective risk management program is the implementation of good documentation practices. Documentation demonstrating that proper procedures were followed at each step establishes a record of appropriate

care in the event that a patient brings a malpractice suit after treatment. To ensure that the documented record is credible and available as a defense, it is therefore critical that all entries be dated and that notations never be altered. To the extent that there is an error in the record, the correction should be made, signed, and dated. The error should be struck through or otherwise denoted as an error, but should remain legible.

Documentation must be thorough to best protect the physician in the event that malpractice litigation arises. At a minimum, the record should include a description of the informed consent process and the patient's consent, any findings, interventions performed, complications, recommendations and patient instructions, and recommended follow-up. Documentation is particularly important when a gastroenterologist is performing an invasive procedure because patients are at an increased risk of experiencing harm. Generally acceptable components of complete documentation for a colonoscopy, for example, include the following:

1. Photographic recording of the cecum and landmarks;
2. Description of the colon preparation, including a recommendation for early repeat of colonoscopy when the preparation is inadequate;
3. Notation of slow and careful withdrawal with adequate clearing of residual pools of liquid;
4. Record of compliance with the informed consent process, including that the physician mentioned the possibility of missed diagnosis;
5. An established process for managing patients' postprocedure questions or complications;
6. A secure method to notify patients and referring physicians of procedure results, including pathology and recommendations for further examinations; and
7. A system to monitor procedure quality and results.<sup>31</sup>

### Clinical Practice Guidelines

Another effective risk management tool in gastroenterology is the use of CPGs. As described earlier, CPGs are evidence-based treatment guidelines developed to assist practitioners determine preferable approaches to treat specific clinical problems.<sup>34,35</sup> CPGs are developed by practitioners (primarily medical societies) based on a variety of sources, such as clinical trials, other peer-reviewed studies, and expert consensus. Because CPGs are developed based on scientific evidence and reflect the practice recommendations of well-respected physicians in the field, adhering to CPGs is one way to improve patient care and reduce the malpractice risk. Nevertheless, it is important to keep in mind that CPGs have limitations. In particular, CPGs may become outdated and no longer represent the standard of care.<sup>36</sup> Physicians are still required to follow and apply advancements in medicine, regardless of the outdated status of the CPG. The quality movement, with quality assessment measures, has a similar impact on standard of care and risk management.

### Best Practice for Managing Complications and Error

The most cautious and meticulous approach to the practice of medicine cannot guarantee that no complications or errors will occur. A significant determinant of the ultimate outcome of such issues is how the physician responds. Although traditional medical training curriculums do not allocate much time to addressing the optimal response,<sup>37</sup> proper management of these issues is important to the patient's health, perception of the physician and likelihood to sue, as well as the avoidance of similar complications or errors in the future. While a normal response

may be to attempt to hide the issue and avoid informing the patient, particularly if the complication arose as a result of error on the part of the physician, this can have dangerous consequences for the patient's health and will likely erode the patient's trust in the physician if he or she ultimately does find out about the error. A more positive and productive response, for example, would be for the physician to promptly inform the patient and their family of the issue, express empathy, and recommend follow-up care. One study of a program instituted at the University of Michigan Health System in 2001, whereby physicians were encouraged to disclose errors to patients and offer compensation, determined that in the 9 years after the program was instituted, claims dropped 36% and lawsuits dropped 65%.<sup>38</sup> Approximately 15 years after the institution of the program, a second study found a 58% drop in claims per patient encounters, despite a 72% increase in clinical activity.<sup>39</sup>

When a complication or error arises, the appropriate response for the physician is to engage in frank discussion and open dialogue with the patient and/or family, provide empathy, and suggest next steps.<sup>40</sup> An empathetic response is always appropriate in the face of an adverse outcome. Physicians should be careful to distinguish offering empathy (i.e., "I am sorry this happened to you") from an apology or admission of error. Engaging with the hospital's risk management team to determine the best course of action can also assist physicians in determining the appropriate response. When a lawsuit is brought, it is important to communicate properly with the risk management department and/or defense attorney and to understand the timeline and proceedings involved in a lawsuit.<sup>40</sup>

## RATIONALE

Upper endoscopy is an important diagnostic tool in the care of patients with gastrointestinal (GI) diseases. Unfortunately, there is a certain amount of discomfort and patient intolerance associated with unsedated procedures. For this reason, physicians are hesitant to use unsedated endoscopy as a first-line of investigation in patients with various GI problems, including gastroesophageal reflux disease (GERD). Thus, proton pump inhibitors are often used as a diagnostic test or for prolonged periods before proceeding to endoscopy. Different approaches have been proposed to improve patient tolerance during upper GI endoscopy. The most common and most widely used approach is intravenous sedation.<sup>1–3</sup> Most patients wish to be sedated for upper endoscopy to avoid discomfort, but sedation introduces the need for numerous guidelines not otherwise required during endoscopy. Pre-, intra-, and postprocedure monitoring and assessment are required. Sedation related issues are responsible for up to 40% of the total endoscopic cost (cost of medication, cost of specialized nursing care, work loss) and one-half of the risk.<sup>1,4</sup> Most patients would prefer to return quickly to normal activities as afforded by unsedated endoscopy.<sup>5</sup> In some countries, general anesthesia is used broadly, which seems extreme for routine upper endoscopy. Less intensive approaches to sedation include premedication, topical anesthesia, and more anecdotal methods (such as ambient music), but they are less effective than intravenous sedation. The goal of all these methods is to reduce the patient's level of sensation, but they fail to modify the nature of the examination itself.

Transnasal introduction has been widely employed for bronchoscopy and laryngoscopy. With the advent of thinner endoscopes, transnasal esophagogastroduodenoscopy (EGD, or upper endoscopy) was originally considered an alternate option when transoral intubation was not possible for anatomical

reasons.<sup>7,8</sup> With time, transnasal intubation appeared to be a logical alternative to standard peroral EGD on a routine basis, as oral intubation of the esophagus is a major source of discomfort for patients.<sup>9</sup> The transoral route induces protective glottal reflexes as the endoscope passes the base of the tongue and is swallowed. With the transnasal route, the patient does not swallow and does not have protective reflexes; patients can control their laryngeal motility and do not feel any sensation of asphyxia, as illustrated by the fact that they are able to talk during the procedure, further decreasing symptoms associated with anxiety.

In this chapter, we will discuss two major topics: tolerance and performance. This association is essential to allow transnasal endoscopy to expand and potentially replace conventional oral endoscopy in certain situations.

## TRANSNASAL ENDOSCOPY

### History

Since the first publications in the 1990s, studies concerning patient tolerance of unsedated transnasal endoscopy have shown conflicting results.<sup>8–12</sup> The authors of one study<sup>13</sup> observed that the overall assessment of patients regarding transnasal endoscopy is worse than with standard endoscopy, whereas another study<sup>14</sup> concluded exactly the opposite. Patient tolerance of transnasal endoscopy is a major issue. The majority of published studies to date are in favor of the transnasal approach. One study of 20 volunteers noted significantly less risk of gagging and vomiting during transnasal insertion.<sup>15</sup> Another evaluated 24 patients who underwent sequential transnasal EGD (5.3-mm diameter scope) followed by standard EGD.<sup>16</sup> The transnasal group had less choking, sore throat, discomfort, and a higher rate of acceptability than the peroral group. A randomized study with 181 patients found tolerance was better with transnasal EGD (5.3-mm

### Abstract

Small-caliber endoscopes are an important tool for the diagnosis and treatment of GI disease. Unsedated transnasal endoscopy is well tolerated and can provide a good optical examination when a detailed assessment of the mucosa is not needed. Thus, it can serve as a first-line option in many centers for exploring GI symptoms, detecting portal hypertension, or screening patients for esophageal neoplasia (squamous cell neoplasia or Barrett's esophagus). Nevertheless, after transnasal detection of a lesion, conventional sedated endoscopy is typically performed to more precisely examine any detected abnormalities and perform treatment. However, several institutions have shown that performing therapeutic interventions, such as argon plasma coagulation or gastrostomy tube placement, using unsedated transnasal endoscopy is feasible, safe, and effective.

Small caliber endoscopes can not only be used to explore the upper GI tract, but can also be utilized in the diagnosis and treatment of bile duct diseases. Several different types of cholangioscopes have been developed and evaluated and three primary techniques are possible: a percutaneous approach, using mother-baby or disposable single operator endoscope systems, and direct peroral cholangioscopy. Due to the fragility of baby scopes, disposable cholangioscopes have been developed, and important optical improvements have recently been added. Disposable scopes have also been tested to explore the upper GI tract to avoid reprocessing and to allow endoscopic procedures to be performed anywhere without the need for a technical platform, but they are not currently used. Capsule endoscopy has become an alternate option to transnasal endoscopy. However, at present, the lack of complete gastric exploration, the inability to perform biopsy samples, and the relatively high cost of the capsule have prevented this technique from replacing standard endoscopy. Finally, although unsedated transnasal endoscopy has shown excellent tolerability and is effective, patients still frequently request sedation for upper endoscopy, and the number of transnasal procedures performed remains relatively low.

capsule endoscopy

diameter) compared to conventional, peroral EGD.<sup>27</sup> This study found that only 3% of patients undergoing transnasal endoscopy desired sedation on a future exam versus 15% in the peroral group. Another study that enrolled 60 patients observed that patients undergoing transnasal endoscopy (5.3-mm diameter) rated the procedure only slightly less comfortable than those undergoing sedated conventional endoscopy. Unsedated transnasal endoscopy was associated with significantly less procedure and recovery room time.<sup>28</sup> One researcher placed 150 patients into three groups to elucidate the respective effect of the nasal route versus the small endoscope diameter on the patient's level of tolerance.<sup>29</sup> One group had an oral route with a 9.8-mm diameter endoscope, the second group had an oral route with a 5.9-mm diameter endoscope, and the third group had a transnasal route (5.9 mm). They found less choking and nausea in the transnasal route group and therefore concluded that the tolerance was dependent on the route and not the endoscope diameter. A similar study was conducted on 150 patients.<sup>30</sup> The authors observed that an ultrathin instrument was better tolerated and required less sedation than conventional endoscopes. Whereas the transnasal route caused less gagging than the peroral route, the tolerance was more dependent on the diameter of the endoscope than on the route of passage. This was demonstrated by the improvement noted with transnasal scopes with only two-way tip deflection, which have a reduction in diameter from 5.5 mm (four-way tip deflection) to 4.9 mm. Finally, a comparative prospective study demonstrated that improved tolerance and less nasal pain was associated with the use of smaller diameter endoscopes when transnasal access was utilized.<sup>31</sup> An example of a transnasal procedure is presented in Video 11.1.

### Is the Nasal Route or the Smaller Endoscope Easier to Tolerate?

Four randomized studies have compared the nasal route and the oral route using ultrathin endoscopes. One study used 5.3-mm and 5.9-mm diameter endoscopes in 170 unsedated patients.<sup>32</sup> The authors found the tolerance similar in the two groups. In contrast, another author demonstrated better tolerance with a 4.9-mm two-way tip deflection scope versus a 5.5-mm nasal scope.<sup>33</sup> One researcher enrolled 60 patients in a study comparing the unsedated transnasal and peroral routes using a 6-mm endoscope for both routes.<sup>34</sup> Overall, tolerance was similar in both groups. The main difference found was that the transnasal group had significantly more nasal pain on insertion and thus 85% of the patients in the transoral group versus only 69% in the transnasal group were willing to undergo unsedated endoscopy in the future ( $p = 0.07$ ). In the fourth study, researchers randomized 260 patients undergoing EGD to have it performed with an ultrathin transnasal (6-mm videoendoscope), an ultrathin oral (6-mm videoendoscope), or standard endoscope (9.6-mm videoendoscope).<sup>35</sup> The study results were not in favor of the transnasal route; the overall assessment was better for standard EGD. However, gagging was reduced in transnasal endoscopy. Of note, it is often gagging that makes oral intubation difficult, thus necessitating increased sedation. It is therefore important to note that all these studies have noted less gagging with the transnasal approach.

### How Can We Explain Tolerance Discrepancies Between Different Studies?

Optimal preparation of the patient is a key factor in achieving improved tolerance. First, a topical anesthetic (lidocaine) has to

be administered with pledgets or by spraying deeply within the nostrils at least 5 minutes prior to endoscope insertion.<sup>31,32</sup> Second, a topical vasoconstricting agent (naphazoline) should be administered as an adjunct to the anesthetic drug to enlarge the nasal passages. Finally, a pharyngeal local anesthetic should be administered at the same time. However, these preparation factors likely do not explain the differences observed. In fact, it is likely that the endoscopists themselves have a large influence on patient preferences. The method of presentation and explanation of the study, as well as the way the questionnaire is obtained, are probably decisive factors (e.g., in one study, patients were questioned by an assistant nurse who did not attend the endoscopy procedure), and the opinions of the patients could reflect the opinions of the endoscopists.<sup>31,32,35</sup> Additionally, if patients are questioned after some time has elapsed since the procedure, their responses may change. The manner in which the patients are recruited may also explain the mixed results, and education is also an important factor. At some institutions, transnasal endoscopy has become the initial approach to EGD, and all patients receive transnasal endoscopy as the initial method of upper endoscopy. Patient age does not seem to affect tolerance of transnasal endoscopy, as demonstrated in a comparative study between young and older patients.<sup>31,35</sup> In a recent meta-analysis including 6659 patients, the technical success of transnasal endoscopy was slightly reduced compared to transoral (~2% lower) but tolerance was significantly improved, with 63% of patients preferring transnasal endoscopy to oral endoscopy.

## Results

### Technical Success

Several studies highlight the trade-off between the potential improved tolerance of transnasal endoscopy and the concomitant loss of diagnostic accuracy. One issue is the higher rate of failure to pass the endoscope into the second portion of the duodenum via a transnasal approach. These technical problems are related to the smaller scope diameter and increased flexibility. In one study, the failure rate was 18% with transnasal endoscopy versus 3% for peroral endoscopy. A higher transnasal failure rate was also found in a second study.<sup>36</sup> The failure to intubate the duodenum via the transnasal route is due to a combination of factors. First, endoscopists are less familiar with this approach, as they are traditionally taught the peroral method. However, the technical success of transnasal endoscopy can be quickly improved with a rapid self-learning curve for experienced endoscopists.<sup>37</sup> Second, due to its more flexible nature, looping occurs frequently in transnasal endoscopy, often making it impossible to reach the second duodenum. The final and likely most important factor is the size of the nasal passage compared to the oral passage. It is the diameter of the endoscope (5.3 mm vs. 5.9 mm) that accounts for the significantly higher proportion of failures (8 of 41 vs. 2 of 43 for the 5.9- vs. 5.3-mm scope, respectively).<sup>38</sup> The larger diameter also accounted for the significantly higher proportion of epistaxis (12 of 33 vs. 4 of 41). The difference in diameter of the 5.3-mm fiberscope versus the 5.9-mm videoscope may account for the differing results seen in published studies. Similar results were demonstrated using a 4.9-mm endoscope compared to a 5.9-mm two-way tip deflection transnasal scope (Olympus, Tokyo, Japan), with a 97.6% success rate for the 4.9-mm scope versus an 88.8% success rate for the 5.9-mm scope ( $p < 0.05$ ). A meta-analysis has demonstrated the effectiveness of transnasal endoscopy, with a 95% technical success rate versus a 97.8% rate with the transoral route (difference:

–2%, confidence interval [CI] –4% to –1%); however, this difference was not significant if a smaller endoscope (< 5.9 mm) was used (difference: –1%, CI –3% to 0.9%).<sup>25</sup>

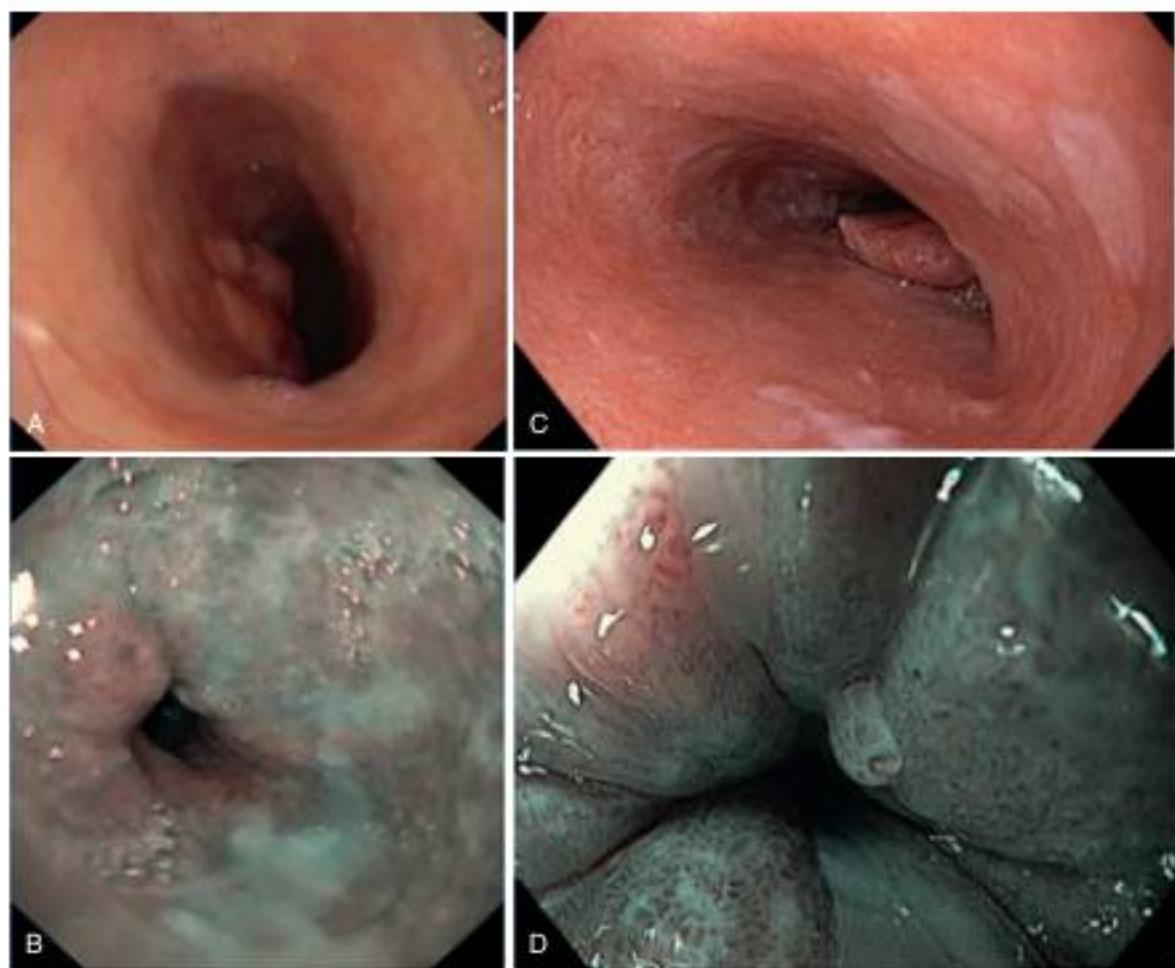

#### Procedure Length

In two studies comparing the transnasal and transoral technique,<sup>17,20</sup> the examination time was 2 minutes longer in the transnasal group than in the transoral group, but this was not observed in a third study.<sup>24</sup> The reason for these differing results is ambiguous and the previously discussed meta-analysis did not analyze procedure time. On one hand, the transnasal approach could be longer, as suctioning of the gastric juice is more difficult and analysis of the mucosa is more challenging. Improved endoscope maneuverability using four-way 5.5-mm diameter endoscopes reduces procedure duration compared to two-way angulation 4.9-mm endoscopes in gastric cancer screening.<sup>26</sup> This difference may also be explained, however, by improved patient tolerance via the transnasal route that permits a more comfortable and thus longer analysis of the mucosa, especially within the stomach, whereas with the transoral

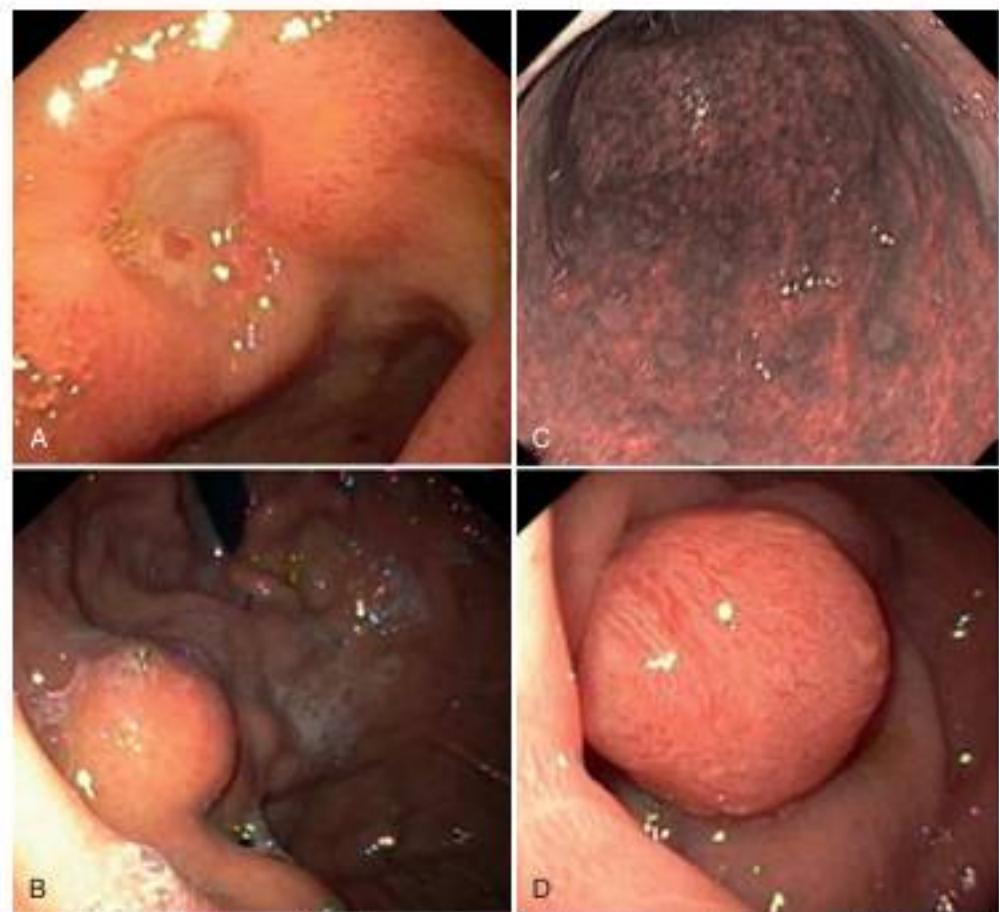

route, the operator may perform an expedited exam to reduce discomfort.

#### Optical Diagnostic Quality

Despite the improved patient tolerance with the unsedated transnasal approach, decreased optical quality has been observed with the thin, 5.3-mm fiberoptic scope (Fig. 11.1).<sup>27</sup> This may lead to missed lesions. The authors of one study noted a sensitivity of 89% for the transnasal approach,<sup>28</sup> and in another study using the ultrathin endoscope, 5 out of 59 endoscopic findings that were identified on standard endoscopy were missed.<sup>11</sup> Due to the smaller channels, the air/water and suction were suboptimal when compared to present conventional upper endoscopes. Sacrificing optimal visualization for a small diameter is a challenging trade-off. Recently, image quality has been dramatically improved in transnasal video endoscopes with virtual chromoendoscopy (such as narrow band imaging [NBI; Olympus] and FUJI Intelligent Chromo Endoscopy [FICE; Fujinon, Fujifilm Medical Co., Saitama, Japan]).<sup>28,29</sup> Nevertheless, transnasal endoscopy is typically used for evaluating upper GI symptoms,

**FIG 11.1** Example of an esophageal carcinoma viewed with a transnasal endoscope (Olympus N180, Tokyo, Japan) and a conventional gastroscope (Olympus HQ 190, Tokyo, Japan). **A**, Transnasal endoscopy picture with white light imaging. **B**, Transnasal endoscopy picture with narrow band imaging. **C**, Conventional endoscopy picture with white light imaging. **D**, Conventional endoscopy picture with narrow band imaging and dual focus magnification.

**FIG 11.2** Example of upper GI pathology viewed with a transnasal endoscopy. **A**, Ulcer in the antrum. **B**, Gastroesophageal varices. **C**, Intestinal metaplasia in the antrum using NBI. **D**, Antral hyperplastic polyp.

suspected portal hypertension, and screening for Barrett's esophagus (Fig. 11.2), but not for the precise examination of preneoplastic lesions, for which upper GI scopes with zoom capability are preferred (see Fig. 11.1).<sup>30,31</sup>

#### Adverse Events

Epistaxis is the major side effect of transnasal gastroscopy. For some authors, use of the 5.9-mm videoendoscope resulted in epistaxis in 36% of patients, whereas the 5.3-mm endoscope was associated with epistaxis in 10% of cases. In a large study with 450 transnasal endoscopy procedures, the rate of epistaxis was 5.8%, all of which resulted in limited bleeding.<sup>32</sup> In one series, the epistaxis rate was only 2%.<sup>33</sup> In addition to epistaxis, vertigo may occur after administration of nasal topical anesthesia, probably due to the passage of lidocaine into the inner ear through the eustachian tube.

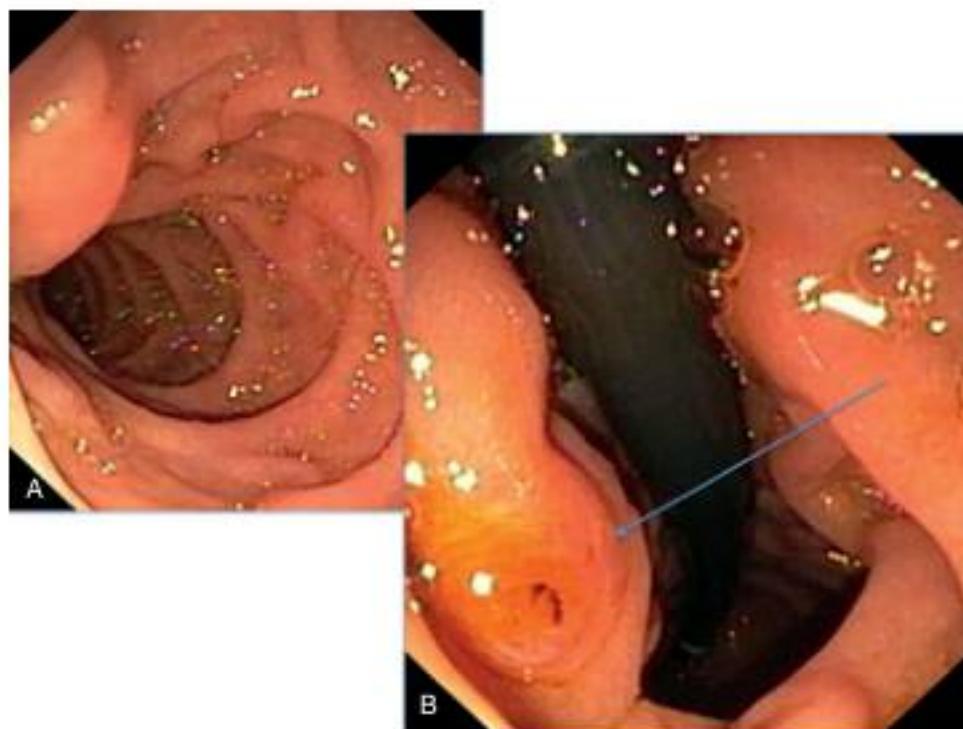

#### Biopsy Sampling

Several studies have demonstrated that biopsy sampling can be performed successfully using the small diameter endoscope with a pediatric biopsy forceps (1.8 mm).<sup>34,35,36</sup> The quality of sampling was found to be satisfactory by a histopathologist. In a 2010 prospective comparative study, 1355 biopsy samples were examined, and their quality was analyzed by expert pathologists. The mean size of samples was inferior when the 1.8-mm diameter

pediatric forceps was compared to a 2.2-mm diameter forceps ( $p < 0.01$ ), but the mucosal depth and specimen quality needed to achieve a definitive histologic diagnosis were similar.<sup>37</sup>

#### Specific Diagnostic Indications

As previously discussed, despite recent improvements in imaging with newer devices, transnasal endoscopy does not provide imaging comparable to standard upper endoscopes because standard endoscopes have a 9-mm diameter and are equipped with zoom lenses, a powerful light source, and better charge-coupled device or complementary metal-oxide semiconductor technology.<sup>38</sup> Thus, when high-resolution picture quality is needed, such as for detection of gastric neoplasia, lesion characterization, and margin delineation, most experts use sedated transoral endoscopy with standard endoscopes to reduce discomfort from longer procedures (as inspection is often done using white light, virtual chromoendoscopy, and dye) and maximize visualization. On the other hand, some lesions are not endoscopically challenging and can easily be detected by transnasal endoscopy, such as ulcers, esophagitis, varices, and Barrett's esophagus.<sup>39,40</sup> Furthermore, some of these easy to diagnose lesions occur in patients with severe comorbidities, making sedated procedures challenging and dangerous. In these cases, unsedated procedures aid in reducing patient risks and allow for repeated procedures during follow-up with good patient acceptance.

**FIG 11.3** Demonstration of the flexibility of transnasal endoscope. **A**, Anterograde view of the second duodenum and the ampulla. **B**, Duodenal retroflexion with retrograde imaging of the major papilla.

### Anatomical Reasons

Transnasal endoscopy is sometimes the only viable option when the oral route is not accessible. This is true for patients with trismus or after tongue surgery.<sup>30</sup> Due to its excellent flexibility, transnasal scopes allow for retroflexion almost everywhere in the digestive tract. For example, retroflexion is possible in the second duodenum to optimize visualization of the papilla when an ampullary adenoma is suspected (Fig. 11.3).

### Esophageal and Pharyngeal Cancer Screening

High-risk patients, including those with a history of head and neck cancers, have an increased risk of esophageal and pharyngeal cancers. In addition, they may have consequences of tobacco or alcohol use such as respiratory or chronic liver disease. Thus, unsedated procedures are beneficial by avoiding sedation and intubation, particularly for patients with a history of ear, nose and throat (ENT) surgery.<sup>31</sup>

Transnasal unsedated endoscopy is significantly more effective than oral endoscopy (98.9% vs. 73.2%,  $p < 0.01$ ) to examine the pharyngeal area; this is due to the better endoscope axis and to a reduction in the gag reflex.<sup>32</sup> Nevertheless, as discussed previously, virtual chromoendoscopy or iodine staining are needed to improve the sensitivity of endoscopic detection.<sup>33-35</sup> The superiority of chromoendoscopy versus white light endoscopy was also demonstrated in transnasal endoscopy with NBI, Lugol staining, and FICE.<sup>32-34</sup> The Valsalva maneuver is a helpful aid to fix the esophagogastric junction and to improve visualization in the lower esophagus.<sup>35</sup> Transnasal endoscopy with chromoendoscopy is an option to detect esophageal cancer in high-risk patients, although prospective comparative studies are needed to demonstrate its noninferiority compared to standard peroral endoscopy.

### Portal Hypertension

Esophageal and gastric varices are easy to diagnose, and patients with cirrhosis typically undergo several endoscopy procedures to detect signs of portal hypertension in the esophagus and stomach. These patients are fragile with severe comorbidities; sedation in these patients can carry significant risk. Transnasal unsedated endoscopy has been studied for this specific indication in several prospective studies, demonstrating superior tolerability compared to transoral endoscopy and with similar effectiveness in diagnosing esophageal and gastric varices, as well as stigmata of recent bleeding.<sup>36-38</sup> Virtual chromoendoscopy with FICE may aid in diagnosing esophageal varices.<sup>39</sup> In cirrhotic patients, capsule endoscopy has also been evaluated to assess patients via a less invasive technique. One study demonstrated improved tolerance with capsule endoscopy with the same diagnostic effectiveness when compared to transnasal endoscopy.<sup>40</sup> All patients in this study preferred capsule endoscopy for their follow-up, but the cost effectiveness of this strategy was not evaluated. Due to its cost, capsule endoscopy is not currently recommended to assess portal hypertension in cirrhotic patients and endoscopy is still the initial option.

### Preoperative Endoscopy Before Bariatric Surgery in Obese Patients

EGD is an important facet of the preoperative evaluation for bariatric surgery. Morbidly obese patients are at high risk for airway complications during sedated procedures, and transnasal EGD is thus an attractive option. This technique is effective in identifying pathology that requires preoperative treatment or long-term follow-up and offers a complete examination with biopsy capabilities to detect *Helicobacter pylori* or preneoplastic conditions.<sup>33,41</sup>

### First Look Endoscopy for Upper GI Bleeding

Upper GI bleeding (UGIB) can be classified into two types a priori according to severity scores: severe bleeding needing resuscitation in intensive care units, and bleeding without hemodynamic consequences that can be medically managed. Patients with severe bleeding usually need intubation and urgent endoscopy to stop the bleeding effectively. In patients with bleeding without hemodynamic compromise, the bleeding source is usually uncertain or due to lesions that can be effectively treated with antisecretory medications such as proton pump inhibitors (esophagitis, ulcer, gastritis). For those patients, transnasal endoscopy is an option to reduce the morbidity of sedated endoscopy. In a prospective study, 145 patients with suspected UGIB were evaluated, and 89 without severe bleeding were considered for transnasal endoscopy.<sup>11</sup> This was effectively performed in 52 cases with five failures; the remainder of the exams were contraindicated for reasons such as patients being on anticoagulant medications. Only two patients had actively bleeding lesions requiring conversion to a sedated endoscopy with intubation.

### Assessing and Traversing Esophageal Strictures

Esophageal strictures are sometimes difficult to evaluate due to the narrowed luminal diameter. Patients with a history of esophageal cancer treated with radiation therapy may develop a stenosis but also have a risk of metachronous esophageal cancer above and below the stricture. Using a small-caliber endoscope via a transnasal or transoral technique is useful to traverse the stricture and to examine the distal esophagus.<sup>30</sup> Furthermore, once the stricture is passed, a guidewire can be safely placed to allow subsequent dilation or stent placement.<sup>31</sup>

### Therapeutic Transnasal Endoscopy

#### Guidewire Placement

Transnasal endoscopy is well suited to certain situations involving guidewire placement.<sup>31</sup> This includes traversing strictures to allow for guidewire placement prior to dilation or stenting as mentioned previously. In addition, transnasal endoscopy has been used for placement of feeding tubes for quite some time, especially for patients with severe comorbidities.<sup>7,8,30,32</sup>

### Transnasal Endoscopic Gastrostomy

Initially used in cases of oral obstruction, transnasal unsedated endoscopic gastrostomy tube placement was subsequently described and evaluated in several studies involving medically fragile patients.<sup>33-37</sup> This technique appears less invasive and is effective and safe when compared to conventional transoral gastrostomy tube placement.<sup>38</sup> It represents a good option in cases of oral obstruction by head and neck cancer.<sup>39</sup> However, the recent description of ostomy metastases in cases utilizing the "pull" technique have changed the approach to this situation.<sup>40-42</sup> Push gastrostomy is now recommended (radiologically or endoscopically) in these situations to avoid metastasis of tumor cells into the gastrostomy tract.<sup>43</sup>

### Argon Plasma Coagulation

The endoscopic diagnosis of gastric vascular ectasia and varices can be improved using virtual chromoendoscopy during transnasal endoscopy, as discussed previously.<sup>43,44</sup> Furthermore, a small-size argon plasma probe has been developed (Erbe, Tübingen, Germany) that can pass through the operating channel of 5.5-mm transnasal scopes to treat lesions. Thus, it is possible to treat

lesions such as gastric antral vascular ectasia and telangiectasia without sedation by argon plasma coagulation in patients with significant sedative risks.<sup>45,46</sup> This technique has also been used in Peutz-Jeghers syndrome to allow for the destruction/ablation of residual hamartomas after resection.<sup>47</sup>

### Endoscopic Resection

Commonly, endoscopic resection requires conventional upper or lower GI endoscopes that have a large operating channel and a water-jet channel to use the relatively large tools needed for resection and to provide adequate lavage in case of bleeding. Nevertheless, there are reports of endoscopic resection using transnasal scopes. The first involved the treatment of Peutz-Jeghers polyps using a combination of snare polypectomy and argon plasma coagulation.<sup>48</sup> Subsequently, a transnasal endoscope was placed in parallel with a conventional endoscope to retract a lesion during a gastric endoscopic submucosal dissection (ESD) procedure.<sup>49-51</sup> More recently (2013), a Japanese team developed a dedicated cap for a transnasal endoscope to perform ESD.<sup>52</sup> This group subsequently described ESD cases in the esophagus and in the duodenal bulb using a transnasal endoscope because of the difficult location in the esophagus and the inability to perform retroflexion with a conventional endoscope in the duodenal bulb.<sup>52,53</sup>

## BILIARY TRACT DIAGNOSIS AND TREATMENT

Small-caliber endoscopes have been increasingly used to access the common bile duct to explore strictures or to perform intracorporeal lithotripsy of bile stones.<sup>54</sup> Three types of cholangioscopy are possible: percutaneously after a period of drainage (to make a mature fistula track), using a mother-baby endoscope system through the operating channel of a duodenoscope, and direct peroral cholangioscopy with or without a guidewire. Whatever the technique used, cholangioscopy allows for the examination and targeted biopsy of strictures, as well as the destruction and removal of stones or polyps. Those techniques have become the first-line option, especially when surgery is not suitable or difficult, such as after liver transplantation or a complex biliopancreatic surgery.<sup>54-57</sup>

### Percutaneous Anterograde Approach

After percutaneous drainage has been performed and an appropriate period of time has elapsed to create a fistula, a small-caliber endoscope (cholangioscope, transnasal scope) can be introduced into the bile duct to evaluate, biopsy, and dilate strictures and to treat (lithotripsy) and remove bile duct stones.<sup>58-60</sup> Although mother-baby endoscopy has been dramatically improved, the percutaneous approach is still used in certain situations.<sup>58</sup> One example is for biliary diseases occurring in patients with a history of digestive surgery and a hepaticojejunum anastomosis (gastric bypass, Roux en Y).<sup>59</sup> In these cases, a jejunal loop is connected to the biliary tree and endoscopic access to the anastomosis is difficult or impossible, even when using single- or double-balloon enteroscopy.<sup>60</sup> In this situation, percutaneous access may be the only option when a repeat surgery is not feasible. A benefit of the percutaneous approach is the maneuverability of the scope, as the distance between the skin and the papilla is short. Furthermore, as the scope is introduced from the liver to the papilla, examination of the distal bile duct just above the papilla is likely easier.<sup>58</sup> This approach allows shorter scopes with better maneuverability to be used.<sup>61</sup> Commonly, percutaneous cholangioscopy

needs two operators and a percutaneous drain that has been present for several weeks or even months to allow for maturation of the fistula track. This long period of drainage may not be well tolerated for many patients, and different strategies avoiding percutaneous drainage have been developed to achieve direct access to the bile duct via the digestive tract.

### Mother-Baby Endoscope System

This technique consists of introducing a small-caliber endoscope into the operating channel of a duodenoscope (4.2 mm) over a guidewire and advancing it over the guidewire across the papilla.<sup>55</sup> The main advantage of this approach is the lack of need for a percutaneous fistula, but serious limitations were initially described. The first types of cholangioscopes appeared in 1985 and were ultrathin fiberscopes.<sup>56</sup> From the beginning, the benefits of the mother-baby system in exploring the middle portions of the bile duct were apparent, although the distal bile duct was easier to visualize and examine by the percutaneous approach. These systems were extremely fragile because they were passed into the duodenoscope and across the elevator and progressively the need for disposable systems appeared. The SpyGlass system (Boston Scientific, Marlborough, MA) was developed to allow examination of the bile duct through a duodenoscope with a reusable optic fiber within a disposable scope.<sup>56,57</sup> The concept was well received, but the maneuverability of the scope and the optical quality of the fiber posed serious limitations.<sup>58</sup> The second-generation SpyGlass device (SpyGlass DS, Boston Scientific) with integrated digital imaging and improved scope mobility has dramatically improved the quality of the system, as demonstrated by several publications.<sup>58,59</sup> This new system allows for high-quality exploration of the bile duct to aid in performing targeted biopsies and lithotripsy through a small operating channel; however, the device is currently quite expensive. Several new disposable cholangioscopes are being developed.

### Direct Retrograde Cholangioscopy

The final solution to access the bile or pancreatic duct is direct cholangiopancreatography using a small-caliber endoscope (transnasal scope, cholangioscope, or pediatric/standard upper endoscope) on a guidewire directly from the mouth to the papilla. If a pediatric/standard upper endoscope is used, a guidewire may not be needed if balloon papilloplasty has been performed on the biliary orifice. This strategy typically involves first performing an endoscopic retrograde cholangiopancreatography (ERCP) to put the guidewire into the duct and then exchanging the duodenoscope over the wire and subsequently inserting the transnasal endoscope or cholangioscope onto this guidewire. Compared to mother-baby systems, the size of the scopes passed over the wire can reach 5.5 mm, and image quality is improved, as is the maneuverability and the mechanical strength of the scope.<sup>58</sup> In addition, even larger pediatric/standard endoscopes can be advanced over stiffer wires or directly inserted into the biliary tree after balloon papilloplasty. The main limitation is that the technical success rate of this option is between 72% and 89% even when using an intraductal balloon to stabilize the guidewire.<sup>58-61</sup>

## DISPOSABLE TRANSNASAL ENDOSCOPES

Finally, a general trend in endoscopy and gastroenterology is to reduce the constraints and costs associated with endoscopy while improving our ability to detect digestive lesions at an early stage,

which is the best approach to improve patient prognosis. For the general population to accept and be compliant with endoscopic screening and follow-up, the examinations must be easy to perform, well tolerated, and inexpensive. Unsedated transnasal endoscopy could be a possible solution, but it is certainly not the only one. Endoscope reprocessing is another constraint related to the practice of endoscopy. It is time consuming, costly, and represents an occupational hazard to the reprocessing staff who have contact with disinfectants. Furthermore, there is still a risk of residual contamination of the endoscope resulting from inadequate reprocessing and, albeit rare, there are no acceptable and effective methods of disinfection for preventing the transmission of prion diseases. One solution for reducing the risk of contamination and the need for disinfection is the so-called disposable-sheathed endoscope. Mayinger et al (1998, 1999) demonstrated the feasibility of disposable-sheathed gastroscopy in 50 patients.<sup>62,63</sup> The performance of endoscopy outside of traditional endoscopy units with reprocessing facilities might be an important advance in achieving a more widespread use of endoscopy. Such a device might be useful should a gastroenterologist feel endoscopy is appropriate immediately after examining a patient in the office and would allow for performance of the procedure within the exam room. The combination of a transnasal route and a disposable sheath may prove to be an attractive alternative for patients by not only resulting in a reduction in health care expenses, but also allowing for earlier detection of digestive tract lesions. Potential applications of this approach could be used in screening for esophageal varices and Barrett's esophagus.

In conclusion, transnasal EGD using small-caliber endoscopes is an important technique in GI endoscopy. It is well tolerated by patients and offers the possibility of performing endoscopy without sedation. Thus, it could significantly bring down the costs and associated risks of EGD. Ongoing improvements and continued development are warranted in the areas of optics and air/water channels before this promising method will replace conventional upper endoscopy. At present, select patients intolerant of peroral endoscopy may benefit from the transnasal approach.

## CONTROVERSIES: COMPETITION WITH CAPSULE ENDOSCOPY

Capsule endoscopy, whose role in the management of obscure GI bleeding is well established, has been utilized since 2004 to examine the esophagus.<sup>64</sup> The three primary applications of esophageal capsule endoscopy involve the detection and follow-up of Barrett's esophagus, the detection of squamous cell carcinoma, and the detection and follow-up of esophageal varices in cirrhotic patients. Capsule endoscopy is a direct competitor to transnasal endoscopy, with its main advantage being the same as that for transnasal endoscopy (i.e., improved patient tolerance). Furthermore, capsule endoscopy also has a major advantage in that it is a single-use device and therefore does not require equipment reprocessing. Capsule endoscopy does not permit complete gastric evaluation, despite the recent ability of a prototype capsule to achieve percutaneous magnetic control, and does not currently provide the ability to sample tissue.<sup>65,66</sup> For these reasons, the potential role of capsule endoscopy for the identification and surveillance of preneoplastic or neoplastic tissue such as Barrett's esophagus or squamous cell carcinoma of the esophagus is limited. For these indications, transnasal endoscopy provides a better option and is also currently less expensive than the disposable capsule.

## INTRODUCTION

Patients who have undergone surgical procedures that altered the upper gastrointestinal (GI) anatomy are often referred for endoscopic evaluation.<sup>1</sup> It is essential for gastroenterologists to understand the postoperative anatomical alterations to select the appropriate endoscope and accessories and obtain meaningful and accurate diagnostic information.<sup>2–5</sup>

This chapter discusses the most common surgical procedures involving the upper GI tract. Technical details and common variations are described for each surgical procedure. The endoscopic correlates to anatomical alterations are described. Available surgical reports should always be reviewed before the endoscopic examination.

## ANTIREFLUX PROCEDURES

### Nissen Fundoplication

Fundoplication is an effective antireflux operation, performed by creating a gastric plication over the distal esophagus just proximal to the cardiosophageal junction to restore the competency of lower esophageal sphincter. This is a standard operative treatment in select patients with gastroesophageal reflux disease (GERD) (Fig. 12.1).<sup>6</sup>

Fundoplication was first described by Dr. Rudolph Nissen in 1955.<sup>7</sup> This procedure is frequently performed along with hiatal hernia surgery.<sup>8,9</sup> A modified technique called a *floppy Nissen fundoplication* can be accomplished by shortening the wrap from 5 cm to 2 cm. Despite being more lax than a conventional Nissen fundoplication, it is equally effective for GERD management, with the additional benefit of a lower incidence of postoperative gas-bloat syndrome or dysphagia. A laparoscopic approach to this procedure has proved to be safe and reliable. Laparoscopic floppy Nissen fundoplication has become the surgical gold standard treatment for GERD.<sup>10–12</sup>

To perform Nissen surgery, the distal esophagus, the cardiosophageal junction, the gastric fundus, and the right and left crura are dissected. Careful dissection is required to avoid transection of the nerve of Latarjet, a branch of anterior vagal trunk supplying the pylorus. Damage to this branch can result in delayed gastric emptying.<sup>13,14</sup> After hernia reduction, the right and left crura are approximated with sutures (see Fig. 12.1A). Division of the short gastric vessels may be required to mobilize the fundus.<sup>15,16</sup> The gastric fundus is mobilized posterior to the cardiosophageal junction, creating a 360-degree wrap by the placement of two or three sutures involving stomach-esophagus-stomach in the anterior portion of the wrap (see Fig. 12.1B1). The anterior and posterior vagus nerves are usually contained in the wrap and attached to the esophagus. At the end of the procedure, the wrap must lie below the diaphragm without tension.<sup>17,18</sup>

During endoscopy, an intact Nissen fundoplication is easily identifiable. During antegrade endoscope passage, the gastroesophageal junction appears tight on visualization, but offers mild resistance to passage of the endoscope. The retroflexed view reveals an encircling redundant mucosa with several parallel rugal folds overlying the gastric cardia, as well as less capacious stomach fundus (see Figs. 12.1B2). Although this is a 360-degree wrap, the redundant fold appears as a 270-degree free cuff margin because the border continuous with the lesser curvature is not evident.<sup>19</sup> The crural closure should maintain the cardia below the diaphragm with the stomach completely insufflated with air. Occasionally, sutures in the distal esophagus may be observed, indicating migration through the wall or inappropriate penetration depth of the stitches during the procedure; this may or may not be associated with symptoms.<sup>20</sup>

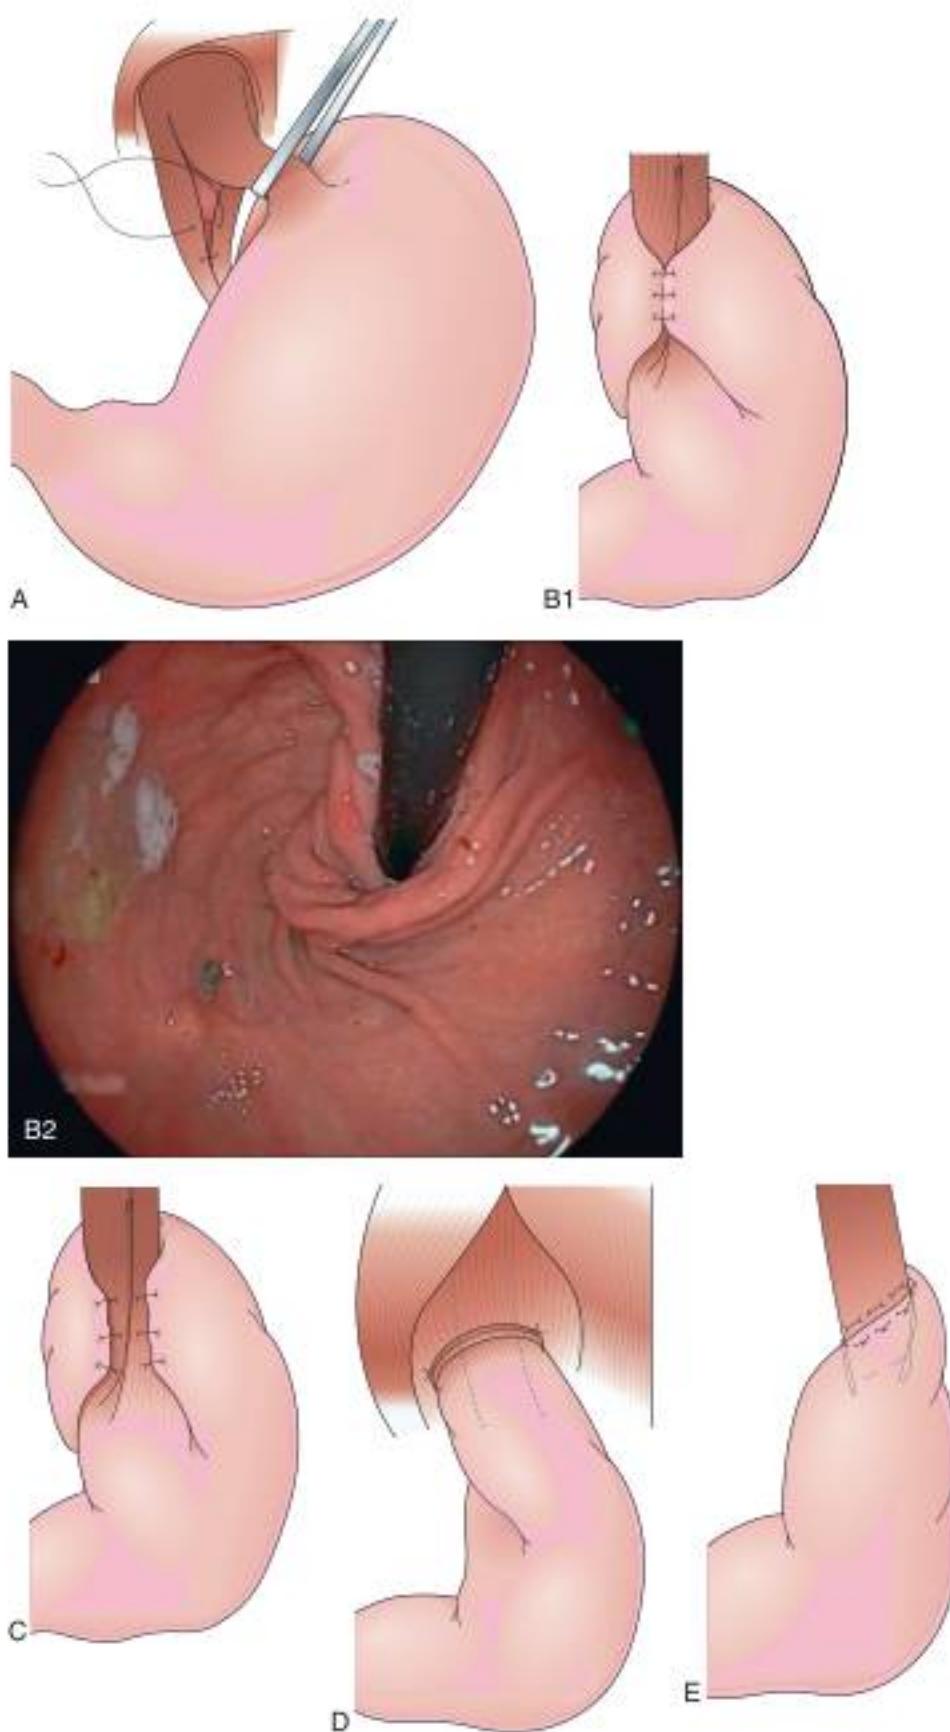

Findings associated with failure of the fundoplication include esophagitis, lack of the encircling fold on a retroflexed view, patulous gastroesophageal junction, migration of the wrap through an enlarged esophageal hiatus, or hourglass appearance

**Abstract**

Patients who have undergone surgical procedures that altered the upper gastrointestinal (GI) anatomy are often referred for endoscopic evaluation. It is essential for gastroenterologists to understand the postoperative anatomical alterations to select the appropriate endoscope and accessories and obtain meaningful and accurate diagnostic information. This chapter discusses the most common surgical procedures involving the upper GI tract. Technical details and common variations are described for each surgical procedure. The endoscopic correlates to anatomical alterations are described. Available surgical reports should always be reviewed before the endoscopic examination.

bariatric surgery

**FIG 12.1** Antireflux procedures. **A**, Esophageal hiatus is narrowed by sutures that approximate the crura of the diaphragm. **B1**, Nissen fundoplication: a short and loose 360-degree wrap is created around the distal esophagus; **B2**, Parallel rugal folds encircle the cardia and the insertion tube of the endoscope. The cardia is below the diaphragm, and there is no hiatal enlargement. **C**, Toupet fundoplication: a posterior partial wrap is created by suturing the edges of the stomach to the anterior esophagus, leaving a space in between. **D**, Dor procedure: a partial anterior fundoplication usually performed following a Heller myotomy. **E**, Belsey-Mark IV procedure: a partial wrap is created through a thoracotomy by progressive invagination of the esophagus into the stomach.

of the proximal stomach (indicating slippage and irregularity in the dome shape of the fundus, which in turn indicates paraesophageal hernia). A squamocolumnar junction located more than 1 cm proximal to the margin of the wrap has been reported to be a major endoscopic clue in diagnosis of postfundoplication problems.<sup>21</sup> An upper GI contrast study can delineate the precise relationship between the wrap and diaphragmatic hiatus when endoscopic examination is unable to clarify if the wrap is intact. Gastric food retention secondary to gastroparesis may be related to damage to the vagus nerves during the procedure.<sup>21</sup> Some patients with persistent dysphagia have a tight wrap that causes resistance to the advancement of the endoscope and these patients may benefit from endoscopic dilation.<sup>22</sup>

### Partial Funduplications (Dor and Toupet)

A partial fundoplication is created with the fundus partially enveloping the distal esophagus, enabling a reduction in post-operative dysphagia and gas-related side effects.<sup>23</sup> A Dor fundoplication is performed anteriorly, and is usually performed in patients who also require a Heller myotomy (see Fig. 12.1C). Toupet fundoplication is performed posteriorly and is best indicated in patients with impaired esophageal body motility (see Fig. 12.1D).<sup>24–26</sup> Partial funduplications also have a prominent fold overlying the cardia, which is less evident than 360-degree wraps when observed endoscopically.<sup>27</sup>

### Belsey Mark IV

The Belsey Mark IV fundoplication requires a thoracotomy. A partial 240-degree anterior wrap is created by the placement of three sutures involving stomach fundus and distal esophagus, resulting in a progressive invagination of the esophagus into the proximal stomach. The crura are also sutured to narrow the esophageal hiatus (see Fig. 12.1E).<sup>28</sup> Endoscopically, the Belsey Mark IV and Nissen funduplications appear similar, with folds encircling the endoscope at the level of the cardia. However, coils of gastric rugae as seen after Nissen repair are not evident, and there is an anterior compression that corresponds to the attachment of the esophagus to the diaphragm.<sup>19</sup>

### Collis Gastroplasty

A short esophagus, usually caused by chronic scarring resulting from GERD, can be repaired surgically through a Collis gastroplasty. This gastroplasty creates a tubular segment of stomach in continuity to the esophagus, long enough to be encircled by a 360-degree fundoplication placed below the diaphragm. The fundoplication around this tubular segment within the positive pressure of the abdomen prevents the gastroesophageal reflux.<sup>29</sup> Short esophagus is identified less often presently, because GERD is diagnosed and treated earlier, reducing the incidence of esophageal scarring and shortening.<sup>10</sup> Endoscopically, the squamocolumnar junction is observed above a short tubular segment of stomach, which may not distend properly because of the wrap. The Collis gastroplasty resembles the Nissen fundoplication on a retroflexed view, except with a less capacious fundus.

## OPERATIONS WITHOUT ALTERATION OF THE PANCREATICOBILIARY ANATOMY

### Billroth I

The Billroth I operation is a type of reconstruction after a partial gastrectomy in which the stomach is anastomosed to

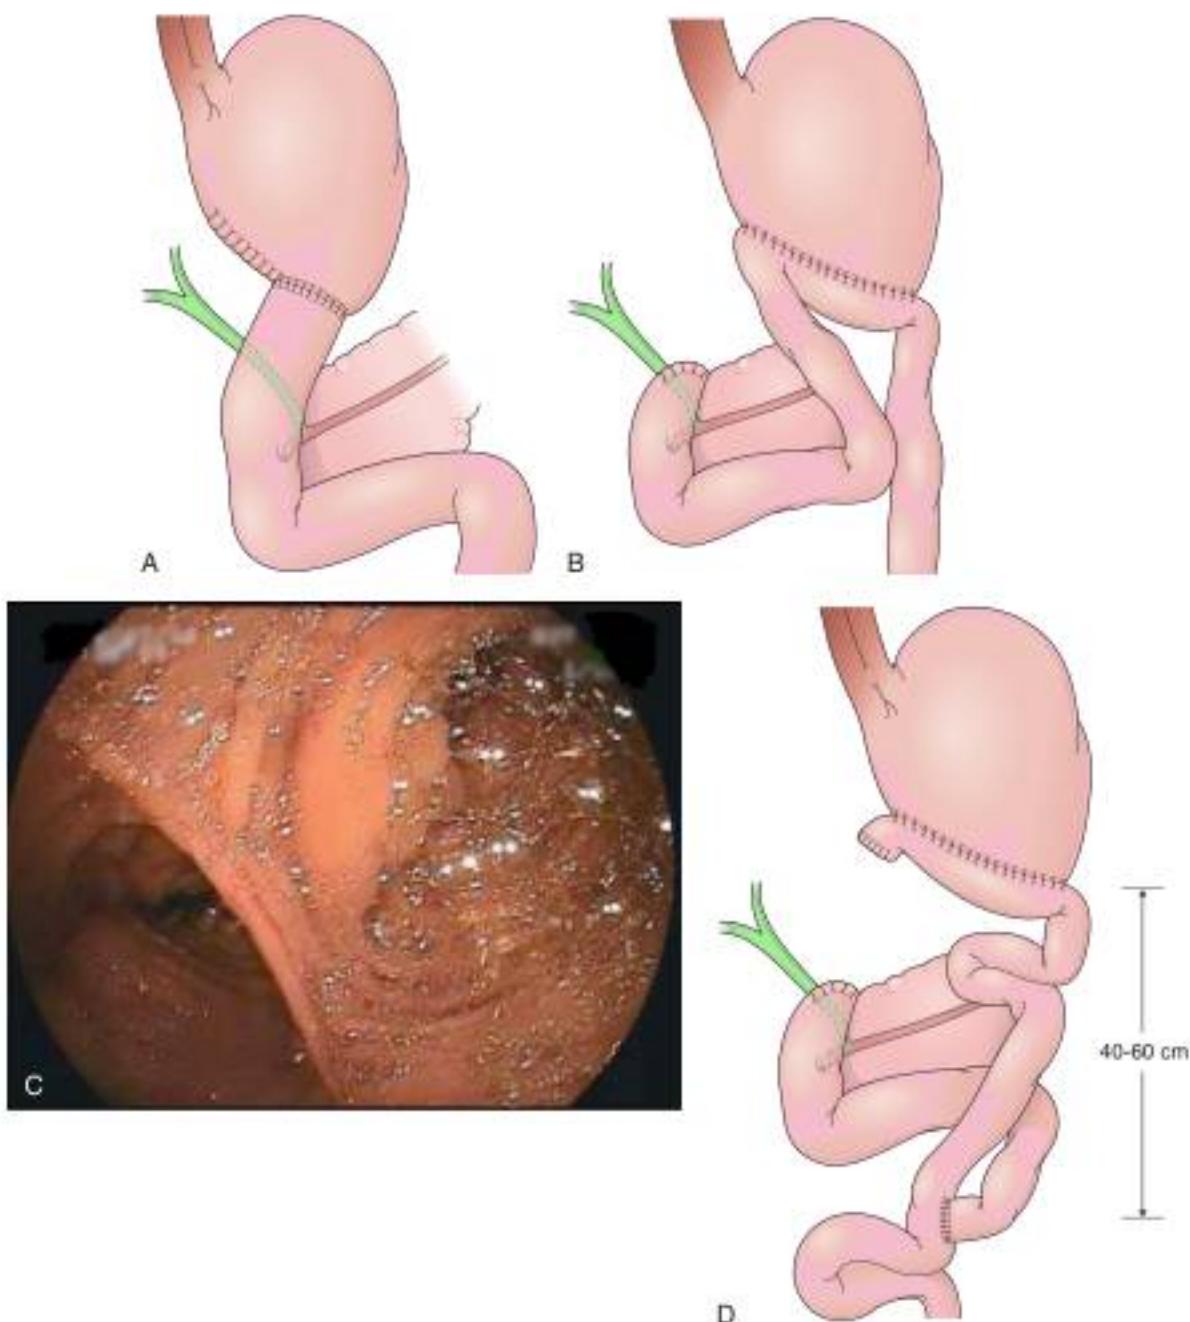

the duodenum (Fig. 12.2A).<sup>30</sup> The gastric resection is usually limited to the antrum, and a truncal vagotomy is often performed in conjunction with the resection. The gastroduodenostomy anastomosis is found toward the greater curvature. A prominent gastric fold representing the closed part of the stomach is often observed along the lesser curvature ending at the gastroduodenostomy. A mucosal pattern change from gastric folds to flat duodenal surface indicates the anastomosis site. The duodenal bulb is partially resected, and the circular folds of the second portion are visualized endoscopically immediately distal to the anastomosis. Major and minor papillae appear to be more proximal in the duodenum than in a patient with intact anatomy. Following the loss of the pylorus, bile reflux is very commonly seen.

### Billroth II

In a Billroth II reconstruction after a partial gastrectomy, the duodenal stump is closed and a gastrojejunostomy is created (see Fig. 12.2B). This type of reconstruction is commonly used for complicated peptic ulcer disease or localized gastric antral carcinoma wherein extensive resection is required. The remaining stomach is variable in length and may allow retroflexion maneuver if an adequate residual stomach remains. The gastric remnant usually contains frothy bile and mucosal erythema from the alkaline reflux.<sup>32</sup> The gastrojejunostomy is located at the distal end of the stomach where two stomal openings corresponding to an end-to-side anastomosis can be identified (see Fig. 12.2C).

There are several variations in surgical technique to perform the gastrojejunostomy, each with a distinct endoscopic appearance. The technique selected depends on surgeon preference, and there is no uniform approach. The gastrojejunostomy can vary with regard to the size of the anastomosis, orientation of the jejunal loop to the stomach, and position of the anastomosis relative to the transverse colon. If the whole length of the transected stomach is anastomosed to the jejunum (oralis totalis or Polya), several rows of jejunal folds are observed between the two stomal openings (Fig. 12.3A). Conversely, if only a segment of the transected stomach is anastomosed to the jejunum (oralis partialis or Hoffmeister), few or no folds are evident. In this case, the stomach is partially closed from the lesser curvature to reduce the diameter of the anastomosis, which is located toward the greater curvature. A prominent fold may be seen emanating from the lesser curvature to the anastomosis. Some surgeons attach the jejunal limb to the suture line that is closing the stomach to prevent dehiscence when performing an oralis partialis anastomosis (see Fig. 12.3B).<sup>33</sup> In this case, a sharp angulation might be negotiated to enter the corresponding jejunal limb. The small anastomosis diameter in association with the sharp angulation of this type of reconstruction may make the anatomy difficult to define endoscopically.

In some cases, the stomach is completely closed at the distal end, and the gastrojejunostomy is performed with a linear or a circular stapler in a side-to-side fashion at the posterior wall, 2 cm proximal to the end of the stomach.<sup>34</sup> When observed endoscopically, however, this side-to-side anastomosis is almost indistinguishable from a short end-to-side anastomosis. The jejunum can be anastomosed to the stomach with the afferent limb attached to the greater curvature (isoperistaltic) or to the lesser curvature (antiperistaltic). The afferent limb refers to the jejunal limb that is in continuity with the duodenum, whereas the efferent limb refers to the one that leaves the stomach toward the distal jejunum. The two stomal openings observed

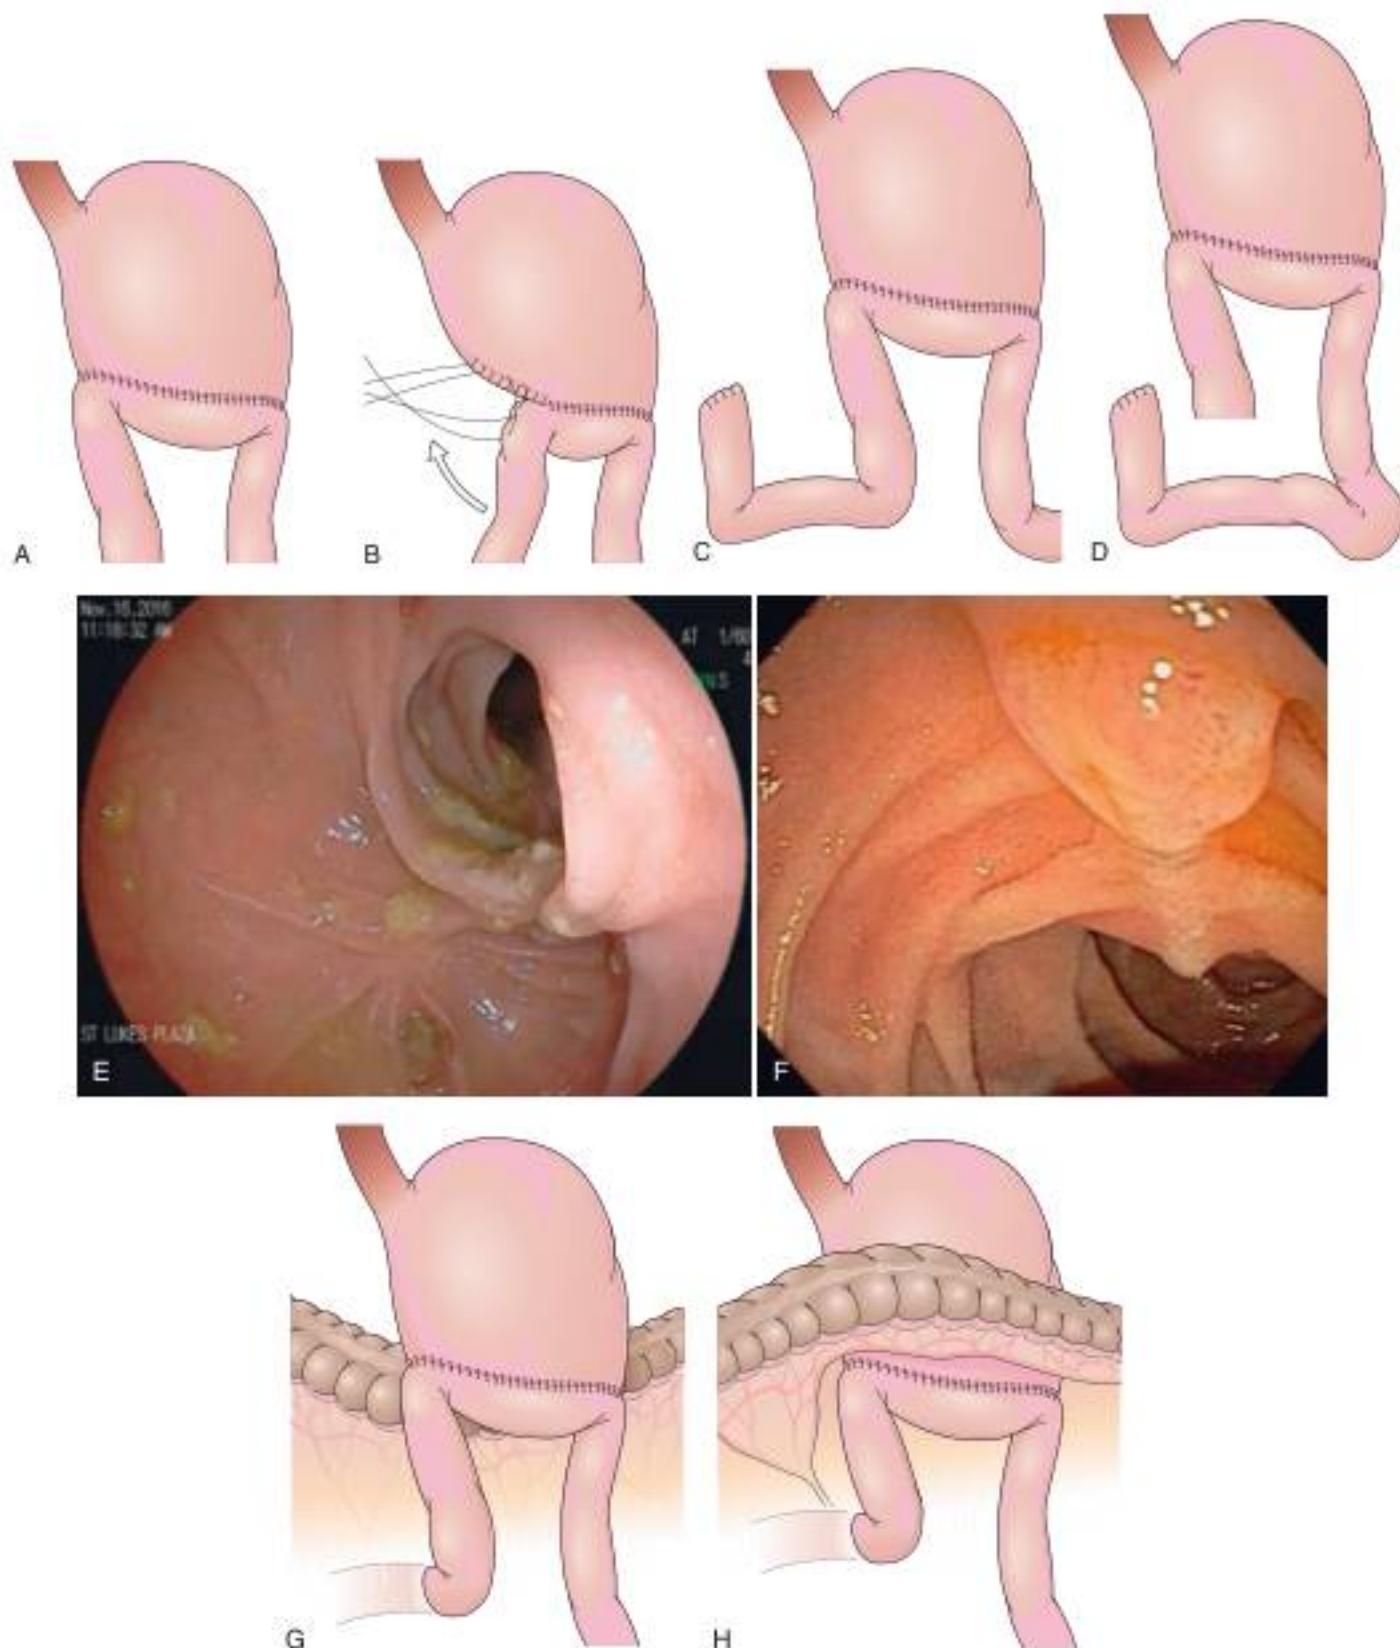

**FIG 12.2** Three types of reconstruction after partial gastrectomy. **A**, Billroth I: a gastroduodenostomy is performed toward the greater curvature. **B**, Billroth II: a gastrojejunostomy is created to reestablish the alimentary transit. Several variations may be observed in this type of reconstruction. **C**, Bile coming from the anastomotic opening linked to the lesser curvature indicates the afferent limb (anisoperistaltic anastomosis). **D**, Roux-en-Y: a gastrojejunostomy only is created with the efferent limb to prevent biliopancreatic reflux into the stomach. A 40-cm to 60-cm efferent limb leads to the jejunojejunostomy and afferent limb.

endoscopically may represent the afferent or efferent limb depending on how the reconstruction was performed (see Fig. 12.3C and D). If the reconstruction is isoperistaltic, the opening linked to the greater curvature corresponds to the afferent limb. If the reconstruction is antiperistaltic, the opening linked to the greater curvature corresponds to the efferent limb. Usually the stomal opening linked to the lesser curvature is more difficult

to access with the endoscope because of the relative tangential approach of the endoscope to the anastomosis (see Fig. 12.3E).<sup>33</sup>

Gastrectomies usually include the lesser curvature more than the greater curvature in the resection. In addition, the information from surgical notes about the type of reconstruction, peristalsis, and bile flow might help define the limbs endoscopically. On careful observation of the anastomosis, bile may be seen coming

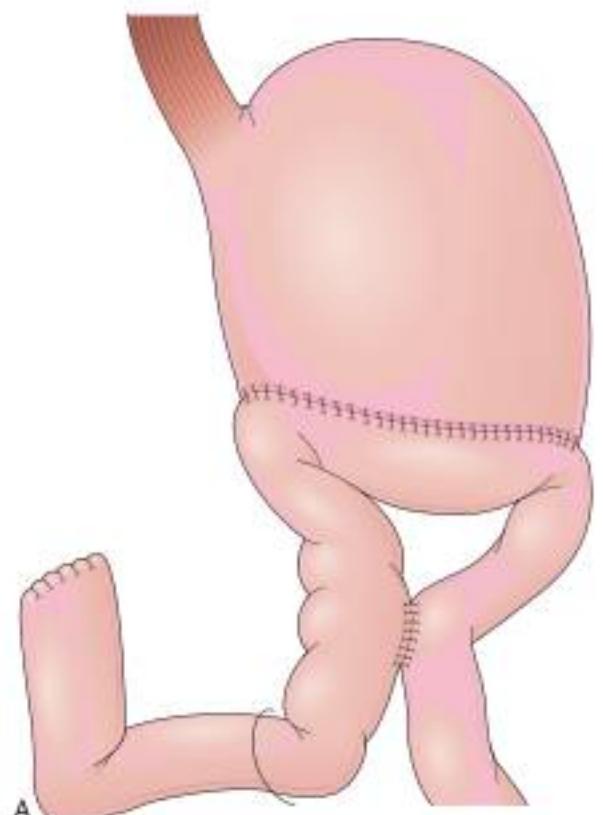

**FIG 12.3** Variations of Billroth II reconstruction. **A**, Oralis totalis (Polya): the anastomosis occupies the entire length of the distal stomach. **B**, Oralis partialis (Hoffmeister): the anastomosis occupies only part of the distal stomach. In some cases, the jejunal limb is sutured to the lesser curvature to protect the suture line of the stomach from disruption. In this scenario, a sharp angulation must be negotiated to advance the endoscope through the stomal opening linked to the lesser curvature. **C**, Antiperistaltic anastomosis: the afferent limb is attached to the lesser curvature. **D**, Isoperistaltic anastomosis: the afferent limb is attached to greater curvature. **E**, Sharp verticalization of the gastroenteroanastomosis impairs advance of the endoscope to this afferent limb. **F**, Retrograde view of the major papilla through the afferent limb. **G**, Antecolic reconstruction: the anastomosis is anterior to the transverse colon leading to a longer afferent limb. **H**, Retrocolic reconstruction: the anastomosis passes through the mesocolon creating a shorter afferent limb.

predominantly from the afferent limb. Introducing the endoscope through this opening should reveal an increasing volume of bile as the endoscope advances toward the bulb, although bile may also be observed in the efferent limb. Visible peristaltic waves advancing away from the endoscope suggest that the instrument is in the efferent limb. When the duodenal stump is reached, the flat mucosa of the residual bulb with a scar-like deformity in a cul-de-sac can be identified. A careful withdrawal of the endoscope exposes the major papilla, usually located at the right upper quadrant at radiography (see Fig. 12.3F).

In patients with Billroth II anatomy, the papilla is rotated 180 degrees in the endoscopic visual field. This "upside down" position requires distinct techniques to perform endoscopic retrograde cholangiopancreatography (ERCP), including dedicated sphincterotomes, needle-knife cut technique over the stent, or balloon dilation of the papilla.<sup>31–35</sup> If the duodenal stump cannot be identified, the endoscope should be withdrawn, and the other limb should be intubated as far as possible. Fluoroscopic visualization may indicate that the efferent limb has been entered when the instrument is seen to pass deep into the pelvis. Conversely, passage of the endoscope into the right upper quadrant toward the liver or previous cholecystectomy clips suggests entry into the afferent limb.<sup>31</sup>

The length of the afferent limb also varies depending on the surgical technique. The afferent limb, naturally fixed at the ligament of Treitz and surgically fixed to the stomach, should be tensionless but not redundant. There are two ways to position the afferent limb in relation to the transverse colon during a Billroth II reconstruction. If an antecolic anastomosis is performed, the gastrojejunostomy is placed anterior to the transverse colon (see Fig. 12.3G). Antecolic reconstructions frequently have long afferent limbs because of the distance between the ligament of Treitz and the remaining stomach, over the mesocolon, omentum, and transverse colon. Conversely, retrocolic reconstructions are performed through an opening in the transverse mesocolon, shortening the distance between the ligament of Treitz and the remaining stomach (see Fig. 12.3H).<sup>42,43</sup> Antecolic and retrocolic anastomoses are similar endoscopically except for the length of the limbs. Caution should be taken if a percutaneous endoscopic gastrostomy is indicated for a patient with a previous partial gastrectomy and retrocolic reconstruction.

Billroth II reconstruction can be created as a side-to-side jeunojejunostomy, referred to as the Braun procedure (Fig. 12.4A).<sup>44</sup> This variant results in an anastomosis between the afferent and the efferent limb to divert bile from the gastric remnant and to release the pressure of the afferent limb, supposedly preventing duodenal stump fistula.<sup>45</sup> The Braun anastomosis is performed 10 to 15 cm distal to the gastrojejunostomy and requires a longer afferent limb to accommodate the jeunojejunostomy.<sup>46</sup> Endoscopically, the gastrojejunostomy is similar to a standard Billroth II. Frothy bile is present in the stomach because the Braun procedure only partially diverts biliopancreatic fluids from the gastrojejunostomy. After advancing the endoscope through either opening of the gastrojejunostomy, the side-to-side Braun anastomosis can be found in the afferent and efferent limb, and three openings can be identified (see Fig. 12.4B). One leads to the distal jejunum, another leads to the afferent limb, and the third one leads back to the stomach. A complete reverse intubation of the stomach may be carried out through the loop created with the Braun anastomosis. The same anatomic landmarks described for other Billroth II procedures are helpful in directing the endoscope through the limbs. However, a

**FIG 12.4 A,** Braun procedure after a Billroth II gastrectomy: an anastomosis between the afferent and efferent limb is created to prevent biliopancreatic reflux to the stomach or alleviate pressure in the afferent limb. **B,** Braun jeunojejunostomy: three openings resulting from a side-to-side enteroanastomosis.

trial-and-error approach may be ultimately necessary to reach the duodenal stump.

A higher rate of perforation has been reported during ERCP while traversing the afferent limb compared with standard ERCP, particularly when a stiff therapeutic duodenoscope is used.<sup>47,48</sup> The Braun procedure has also been associated with perforations during ERCP. The use of a forward-viewing endoscope in these patients can reduce the risk of jejunal perforations.<sup>49</sup> The ability to use a duodenoscope elevator may increase the success of the procedure, and a flexible diagnostic duodenoscope may be safer

than a stiff therapeutic instrument. If the papilla cannot be located with a side-viewing endoscope, the forward-viewing endoscope used should be either a pediatric colonoscope or one of the deep small bowel intubation technologies such as single or double balloon endoscopes to maximize the chances of reaching the papilla.

### Roux-en-Y Gastrectomy

In a Roux-en-Y reconstruction, the jejunum is transected close to the ligament of Treitz, creating two distinct segments. The distal segment is sutured to the gastric remnant (gastrojejunostomy), becoming the efferent limb. The proximal segment is sutured to this efferent limb (jejunojejunostomy) approximately 40 cm below the gastrojejunostomy (see Fig. 12.2D). The proximal segment is called the afferent limb, which connects the duodenum to the efferent limb instead of the stomach as in Billroth II reconstructions. The Roux-en-Y reconstruction prevents biliopancreatic fluids from refluxing into the stomach in patients who have undergone gastric resection. It can be performed as the initial reconstruction after a gastrectomy or as the treatment for postgastrectomy syndrome resulting from a previous Billroth II reconstruction.<sup>50–53</sup> Truncal vagotomy is commonly performed in association with Roux-en-Y to prevent peptic ulcers in the efferent limb, which is no longer washed by the alkaline contents of the biliopancreatic fluid.<sup>54</sup>

The gastrojejunostomy is end-to-side, and two stomal openings are seen. The reconstruction can be oralis totalis or partialis, isoperistaltic or antiperistaltic, and antecolic or retrocolic, as described for Billroth II. In contrast to the Billroth II, one of the two limbs is extremely short and ends blindly almost immediately. On entering a long limb with a patent lumen, it is almost certain that the endoscope is within the efferent limb. If the Roux-en-Y was performed after an initial Billroth II reconstruction, the endoscopist should be aware that the blind limb might be patent for several centimeters before ending in a cul-de-sac. This short segment of patent limb occurs because conversion from a Billroth II to a Roux-en-Y sometimes has to be performed farther from the gastrojejunostomy to avoid adhesions from the initial surgery.

In effective Roux-en-Y reconstructions, the remnant stomach is completely clean of bile (Fig. 12.5A and B). The absence of bile in an operated stomach should always alert the endoscopist for a Roux-en-Y reconstruction, and the presence of residual food in this case should not lead to an erroneous conclusion of efferent limb obstruction. Total obstruction of the afferent limb in a Billroth II reconstruction could also prevent bile to reflux to the stomach, mimicking a Roux-en-Y, but this is uncommon.<sup>55</sup> Conversely, presence of bile does not exclude a Roux-en-Y reconstruction. In this case, a short-length efferent limb may be responsible for the reflux. To be effective, the efferent limb has to measure at least 40 cm from the gastrojejunostomy to the jejunojejunostomy.<sup>56</sup> Longer limbs (up to 60 cm) may also be encountered.<sup>57</sup>

Intubation through the efferent limb usually follows a straight route with variable looping. The enteroenteric anastomosis is usually end-to-side, but it may be side-to-side with a blind end. In either case, the endoscope has to leave the efferent limb and enter the afferent limb to reach the major papilla in the duodenum (see Fig. 12.5C). If a side-to-side anastomosis is present, three openings can be observed. The opening in continuity with the efferent limb leads to the distal jejunum, the second opening leads to a blind distal end of the afferent limb, and the third one

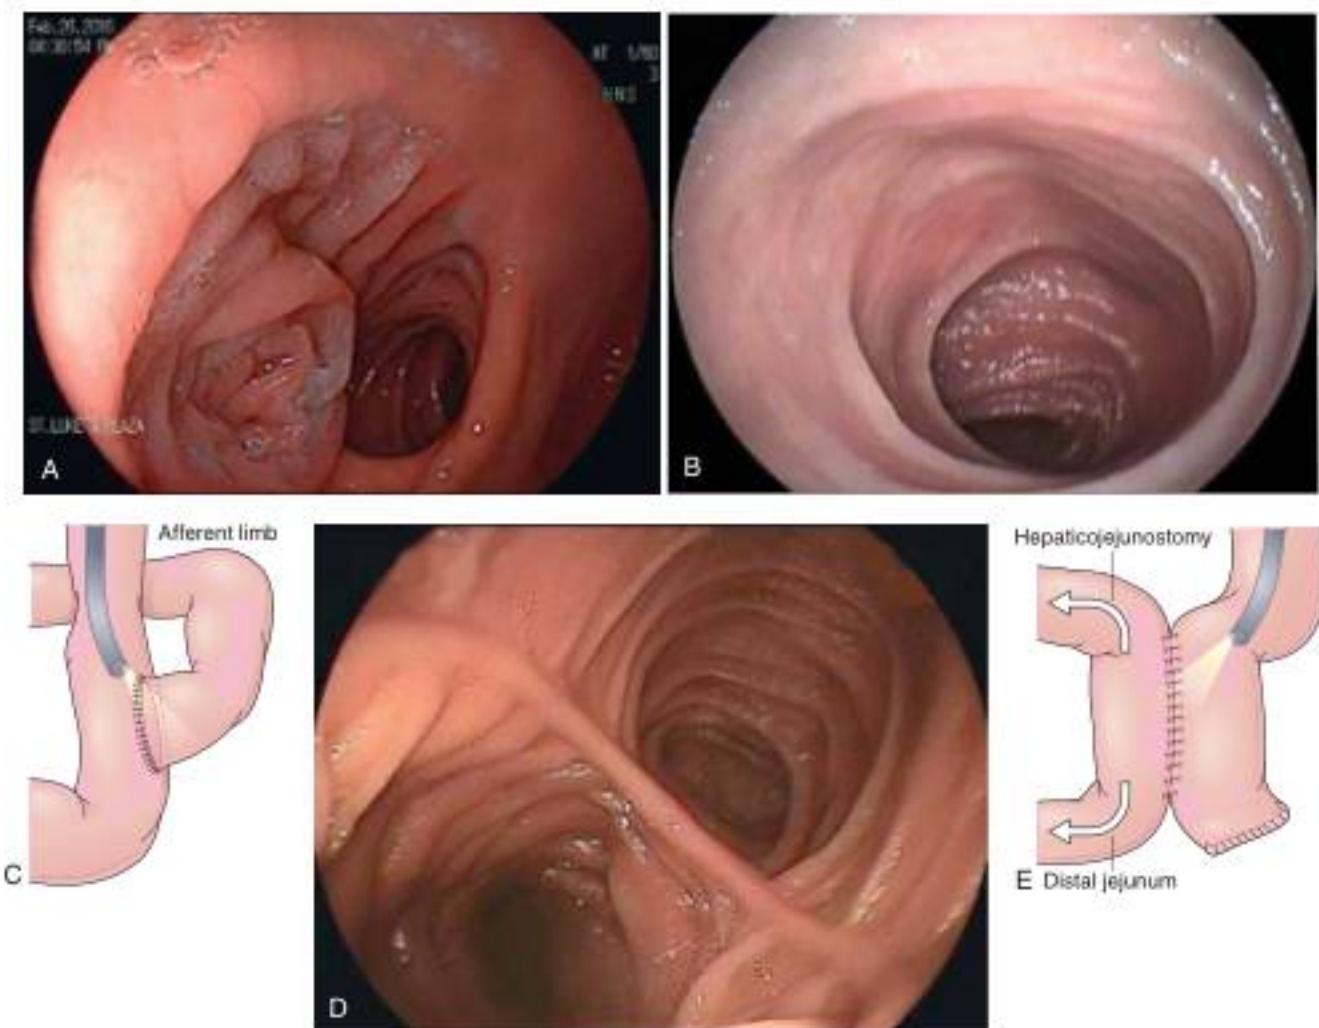

leads to the duodenum through the afferent limb (see Fig. 12.5D). An end-to-side anastomosis has two openings. One is a continuation of the efferent limb and leads to the distal jejunum; the other opening leads to the afferent limb. Different degrees of angulation have to be negotiated to enter the afferent limb depending on the anastomosis configuration. Once the afferent limb is entered, progressively more bile should be seen until the duodenal stump is reached.

A complete visualization of the Roux-en-Y gastrojejunostomy during a routine upper endoscopy can be performed with a forward-viewing gastroscope, including the jejunoojejunostomy. In contrast, if patients require ERCP, a longer insertion tube is usually needed (pediatric and adult colonoscopies, dedicated enteroscopes, single or double balloon enteroscopes).<sup>58</sup> Overtube-assisted enteroscopy (OAE) techniques, single or double balloon enteroscopes, have increased the ability to perform ERCP in patients with altered upper GI anatomy. ERCP success rates are 90% in patients with Billroth II anatomy, 76% in patients who had undergone either a Roux-en-Y or a pancreaticoduodenectomy, pylorus-preserving pancreaticoduodenectomy, or hepaticojejunostomy, and 70% in patients who underwent Roux-en-Y with gastric bypass surgery. Cannulation success rates appeared to be equivalent in patients with both native papilla and biliary-enteric or pancreaticoenteric anastomoses (90%–92%).<sup>59–61</sup>

### Gastrojejunostomy Without Gastric Resection

Gastrojejunostomy without gastric resection is performed to bypass the distal stomach or the duodenum, mostly in cases of malignant obstruction that cannot be resected. In major duodenopancreatic trauma with a high risk for fistulas, a gastrojejunostomy may also be performed in association with a temporary closure of the pylorus as part of the duodenal exclusion.<sup>62</sup> Occasionally, the gastrojejunostomy is created prophylactically during the surgical exploration of a patient with unresectable adenocarcinoma of the head of the pancreas to prevent subsequent gastric outlet obstruction.<sup>63</sup> The gastrojejunostomy is usually performed along the greater curvature of the distal body or the proximal antrum of the stomach (Fig. 12.6A). It may involve the anterior or the posterior wall at the surgeon's discretion. In all cases, a side-to-side anastomosis is performed with the first jejunal loop that can be sutured without tension to the stomach. The anastomosis can be isoperistaltic or antiperistaltic, antecolic or retrocolic, as described for a Billroth II gastroenteroanastomosis. The definition for the length of the anastomosis does not apply (oralis totalis or oralis partialis) because this is a side-to-side anastomosis. However, this anastomosis usually resembles an oralis partialis in length.

The gastrojejunostomy appears endoscopically as a vertical anastomosis with two stomal openings that correspond to the afferent and efferent limbs. Either one of the limbs may be in a superior (upper) or inferior (lower) position, depending on the technique used during the surgery. If an isoperistaltic gastrojejunostomy has been created, the opening of the afferent limb should be expected in the upper position. The endoscopist should look carefully for a gastrojejunostomy in a patient with an upper tract obstruction who had undergone surgery. This anastomosis may become easily overlooked because it is typically not large, usually located among edematous gastric folds, and associated with gastric contents resulting from outlet obstruction (see Fig. 12.6B). Ulcerations are also common and may impair intubation of the jejunal openings resulting from tissue retraction.<sup>64</sup> Access to the papilla can be achieved by passing the endoscope retrograde

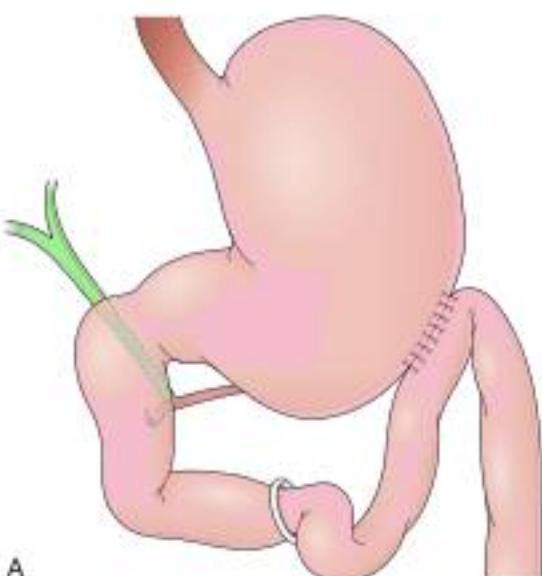

**FIG 12.5** Roux-en-Y gastrectomy. **A**, Gastrojejunostomy clean of bile with two openings (one is short and ends blindly). **B**, Lack of bile in typical Roux-en-Y efferent limb. **C**, Terminolateral anastomosis in a Roux-en-Y gastrectomy: two openings are observed at this level; one leads to the distal jejunum, and the other leads to the ampulla via the afferent limb. **D**, Two openings are at the level of a side-to-side jejunoojejunostomy. The third opening is located proximally and out of the field. Bile is usual at this level where the efferent limb connects to the afferent limb. **E**, Laterolateral anastomosis in a hepaticojejunostomy: the endoscope has passed through the stomach, duodenum, and proximal jejunum reaching the jejunoojejunostomy. Three openings are noted, including a blind one. In contrast to a Roux-en-Y gastrectomy (**A**), the loop in which the endoscope is located ends blindly.

through the afferent limb when a gastric outlet obstruction has been established. The Braun procedure may be added to the gastrojejunostomy as previously described for Billroth II reconstruction (see Fig. 12.6C).

### Bariatric Surgery

Obesity is associated with serious health consequences including hypertension, type 2 diabetes, hyperlipidemia, coronary artery disease, peripheral vascular disease, cerebral vascular accidents, thromboembolic conditions, obstructive sleep apnea, obesity-hypoventilation syndrome, weight-bearing osteoarthritis, nonalcoholic fatty liver disease, hepatic cirrhosis, and an increased risk of developing colorectal and pancreatic cancer.<sup>63–67</sup> Indications for bariatric procedures are increasing because of the increase in

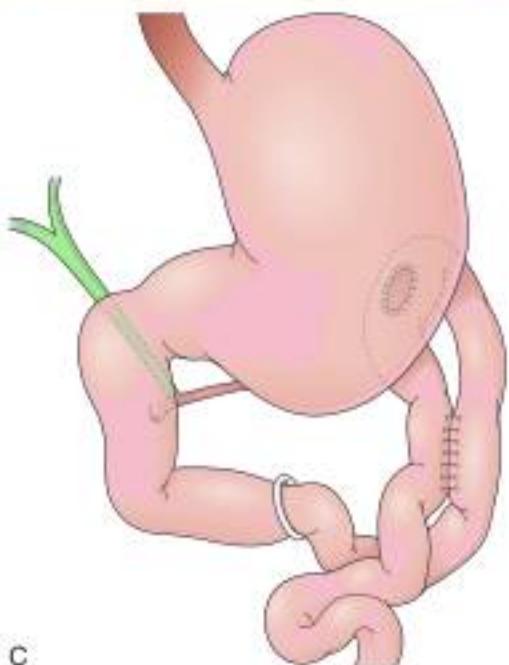

prevalence of obesity, including childhood obesity, and the lack of effective nonsurgical treatments. The National Institutes of Health (NIH) Consensus Conference in 2004 recognized bariatric surgery as the most effective therapy available for morbid obesity and that it can result in improvement or complete resolution of obesity-related comorbidities.<sup>68</sup> Bariatric surgical procedures include laparoscopic or open Roux-en-Y gastric bypass, sleeve gastrectomy (SG), vertical banded gastroplasty (VBG), laparoscopic adjustable gastric band (LAGB), biliopancreatic diversion with duodenal switch (BPD/DS), and laparoscopic mini gastric bypass.<sup>63–67</sup> A growing number of patients with altered anatomy should be expected in endoscopy units because GI complaints are frequent after bariatric surgery. The same complaints in uncomplicated postoperative courses can be present in patients

A

B

C

**FIG 12.6** Gastroenteroanastomosis. **A**, Antiperistaltic gastroenteroanastomosis is created along greater curvature. **B**, Gastrojejunostomy without gastric resection: residual contents, enlarged gastric folds, and suboptimal air insufflation may obscure this anastomosis. **C**, Isoperistaltic gastroenteroanastomosis is created on the posterior wall of the stomach in association with Braun procedure.

with important surgical complications, which may require surgical revision.<sup>68–70</sup> Early post-bariatric surgery complications include early postoperative hemorrhage, anastomotic leak, and fistula. Late complications include anastomotic stricture, marginal ulcer, obscure GI bleeding, and gastric band slippage.<sup>71</sup>

Some endoscopic findings may represent either a normal postsurgical appearance or a complication depending on the surgery that was performed.<sup>71</sup> An example is the endoscopic finding of a communication between a short proximal gastric pouch and a normal-size remnant stomach. This communication is normally expected in a VBG, but it represents a failure (gastrogastric fistula) if the surgical procedure was a gastric bypass (GB). Familiarity with the most common bariatric procedures is essential for optimal endoscopic assistance to bariatric patients and surgeons. Surgical procedures to treat obesity have evolved during the last 6 decades. They can be simplified into two types, restrictive and malabsorptive.<sup>72</sup> Selection of a procedure is based on individual patient characteristics and surgeon preference.<sup>73–75</sup>

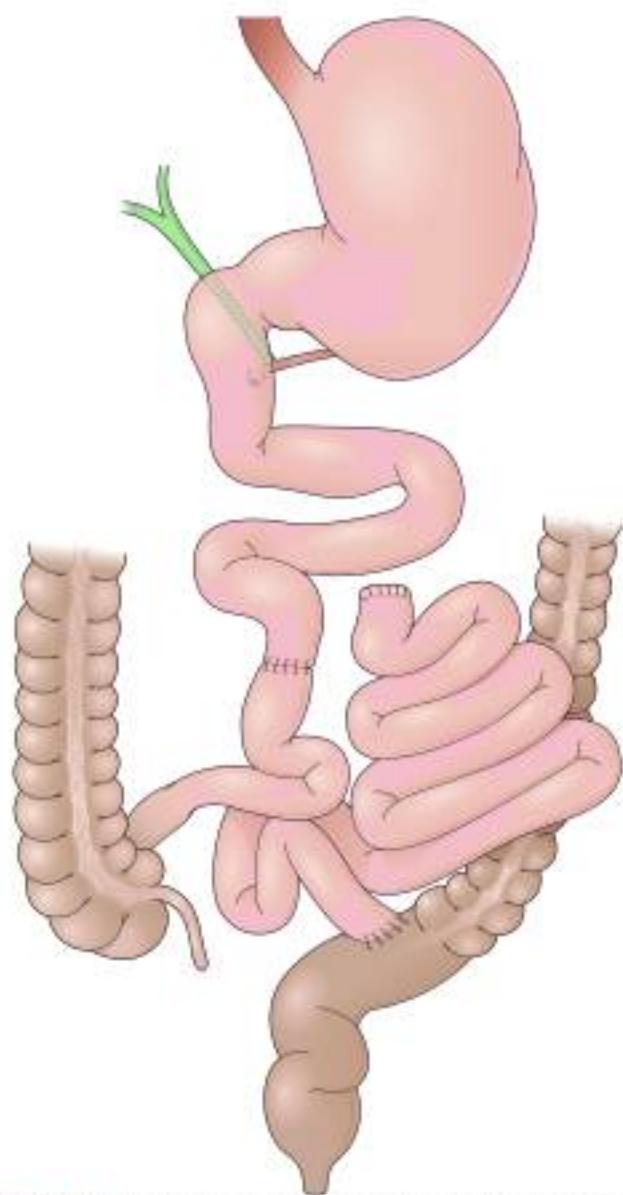

#### Jejunoileal Bypass

Jejunoileal bypass (JIB) was the first procedure proposed to induce malabsorption in 1954.<sup>76</sup> It is technically simple and safe because it involves only enteroanastomosis, and the surgical steps are performed in the middle abdomen. In JIB, the proximal jejunum and the distal ileum are transected. The long jejunoileal segment in between these two transections is excluded from the intestinal transit by closing the proximal margin and connecting the distal margin to the sigmoid colon. An enteroanastomosis is performed between the proximal jejunum and the distal ileum, leaving a short segment of small bowel for absorption (Fig. 12.7). This procedure does not alter the endoscopic anatomy of the upper GI tract. JIB is no longer performed because of severe hepatic complications.<sup>77</sup> Patients with an intact JIB should consider reversion of the operation.

#### Gastric Bypass

GB is a restrictive and malabsorptive procedure.<sup>78</sup> It is the most popular bariatric procedure performed worldwide along with sleeve gastrectomy.<sup>79,80</sup> The operation includes partition of the stomach, creating a small-volume pouch (15 to 50 mL) in the proximal stomach.<sup>78,81</sup> With the distal stomach completely disconnected, the proximal gastric pouch is anastomosed with a Roux-en-Y limb that ranges from 75 to 150 cm in length to reestablish the alimentary transit. The extent of the bypass of the intestinal tract determines the degree of macronutrient malabsorption (Fig. 12.8A).<sup>67,82</sup>

Gastric bypass can be performed by both open and laparoscopic techniques. The laparoscopic approach has a higher rate of intraabdominal complications but a shorter duration of hospitalization, fewer wound complications, and improved postoperative patient comfort.<sup>83</sup> Surgical technical variations can

**FIG 12.7** Jejunoileal bypass. This operation reduces the small bowel absorptive surface and leaves a long, nonfunctional segment of small bowel. Endoscopically, there is no change in the anatomy for upper endoscopy and endoscopic retrograde cholangiopancreatography (ERCP).

be observed in GB in regard to the orientation of the pouch (horizontal vs. vertical), partition of the stomach (transection vs. no transection), use of a Silastic ring around the gastrojejunostomy stoma, and the length of the Roux-en-Y limbs.<sup>15–17</sup>

The procedure proposed by Capella et al (2002)<sup>18</sup> incorporates a Silastic ring in the upper gastric pouch to prevent late stretching and the suturing of the Roux-en-Y limb to the staple line of the pouch to prevent late gastrogastric fistulas (see Fig. 12.8B–D).

For the endoscopist, GB may be compared with a Roux-en-Y gastrectomy. The differences are the size of the proximal gastric pouch, the length of the Roux-en-Y limb, and the fact that the distal stomach is not resected. Upper endoscopy in a patient with GB shows a small proximal pouch immediately after the esophagogastric junction with a narrow stoma leading to the

small bowel and a long limb before reaching the jejunoojejunostomy, which may be inaccessible depending on the length of the limb (see Fig. 12.8E). The gastric partition may include only the staple line, without division of the stomach (undivided bypass), or a complete transection of the stomach (divided bypass) (see Fig. 12.8F). Undivided bypass presents a higher rate of fistulas between the pouch and the distal stomach compared with divided bypass. A gastrogastric fistula leads to a failure in weight loss and to a higher incidence of peptic ulcers beyond the gastrojejunostomy.

The gastrojejunostomy may be to the side or to the end of the jejunum or stomach. The small gastric pouch makes lateral and terminal gastric anastomoses indistinguishable. However, lateral and terminal anastomoses are different on the jejunal side. A lateral jejunal anastomosis has two openings. One ends blindly shortly after the anastomosis; the other leads to the distal jejunum (efferent limb) (see Fig. 12.8G). A terminal anastomosis has one opening that should be readily accessible endoscopically. The blind end of a lateral anastomosis should not be confused with stenosis of the efferent limb, particularly when scarring alters the anatomy. Abnormal endoscopic findings include esophagitis, pouch or esophagus dilation, stomal stenosis, stomal ulceration, prosthesis erosion at the stoma, and breakdown of the partition staple line. Stomal ulceration has been related to staple line dehiscence in which a gastrogastric fistula occurs, although other factors may be involved.<sup>17,18</sup>

Access to the major papilla and to the disconnected part of the stomach is often impossible transorally in patients with GB using regular endoscopes.<sup>19–21</sup> A percutaneous gastrostomy tract created in the distal stomach is used as an alternative to access these areas with the endoscope.<sup>22,23</sup> Double-balloon and single-balloon enteroscopy has emerged as an alternative to access the biliopancreatic ducts and the disconnected part of the stomach in these patients.<sup>24–27</sup>

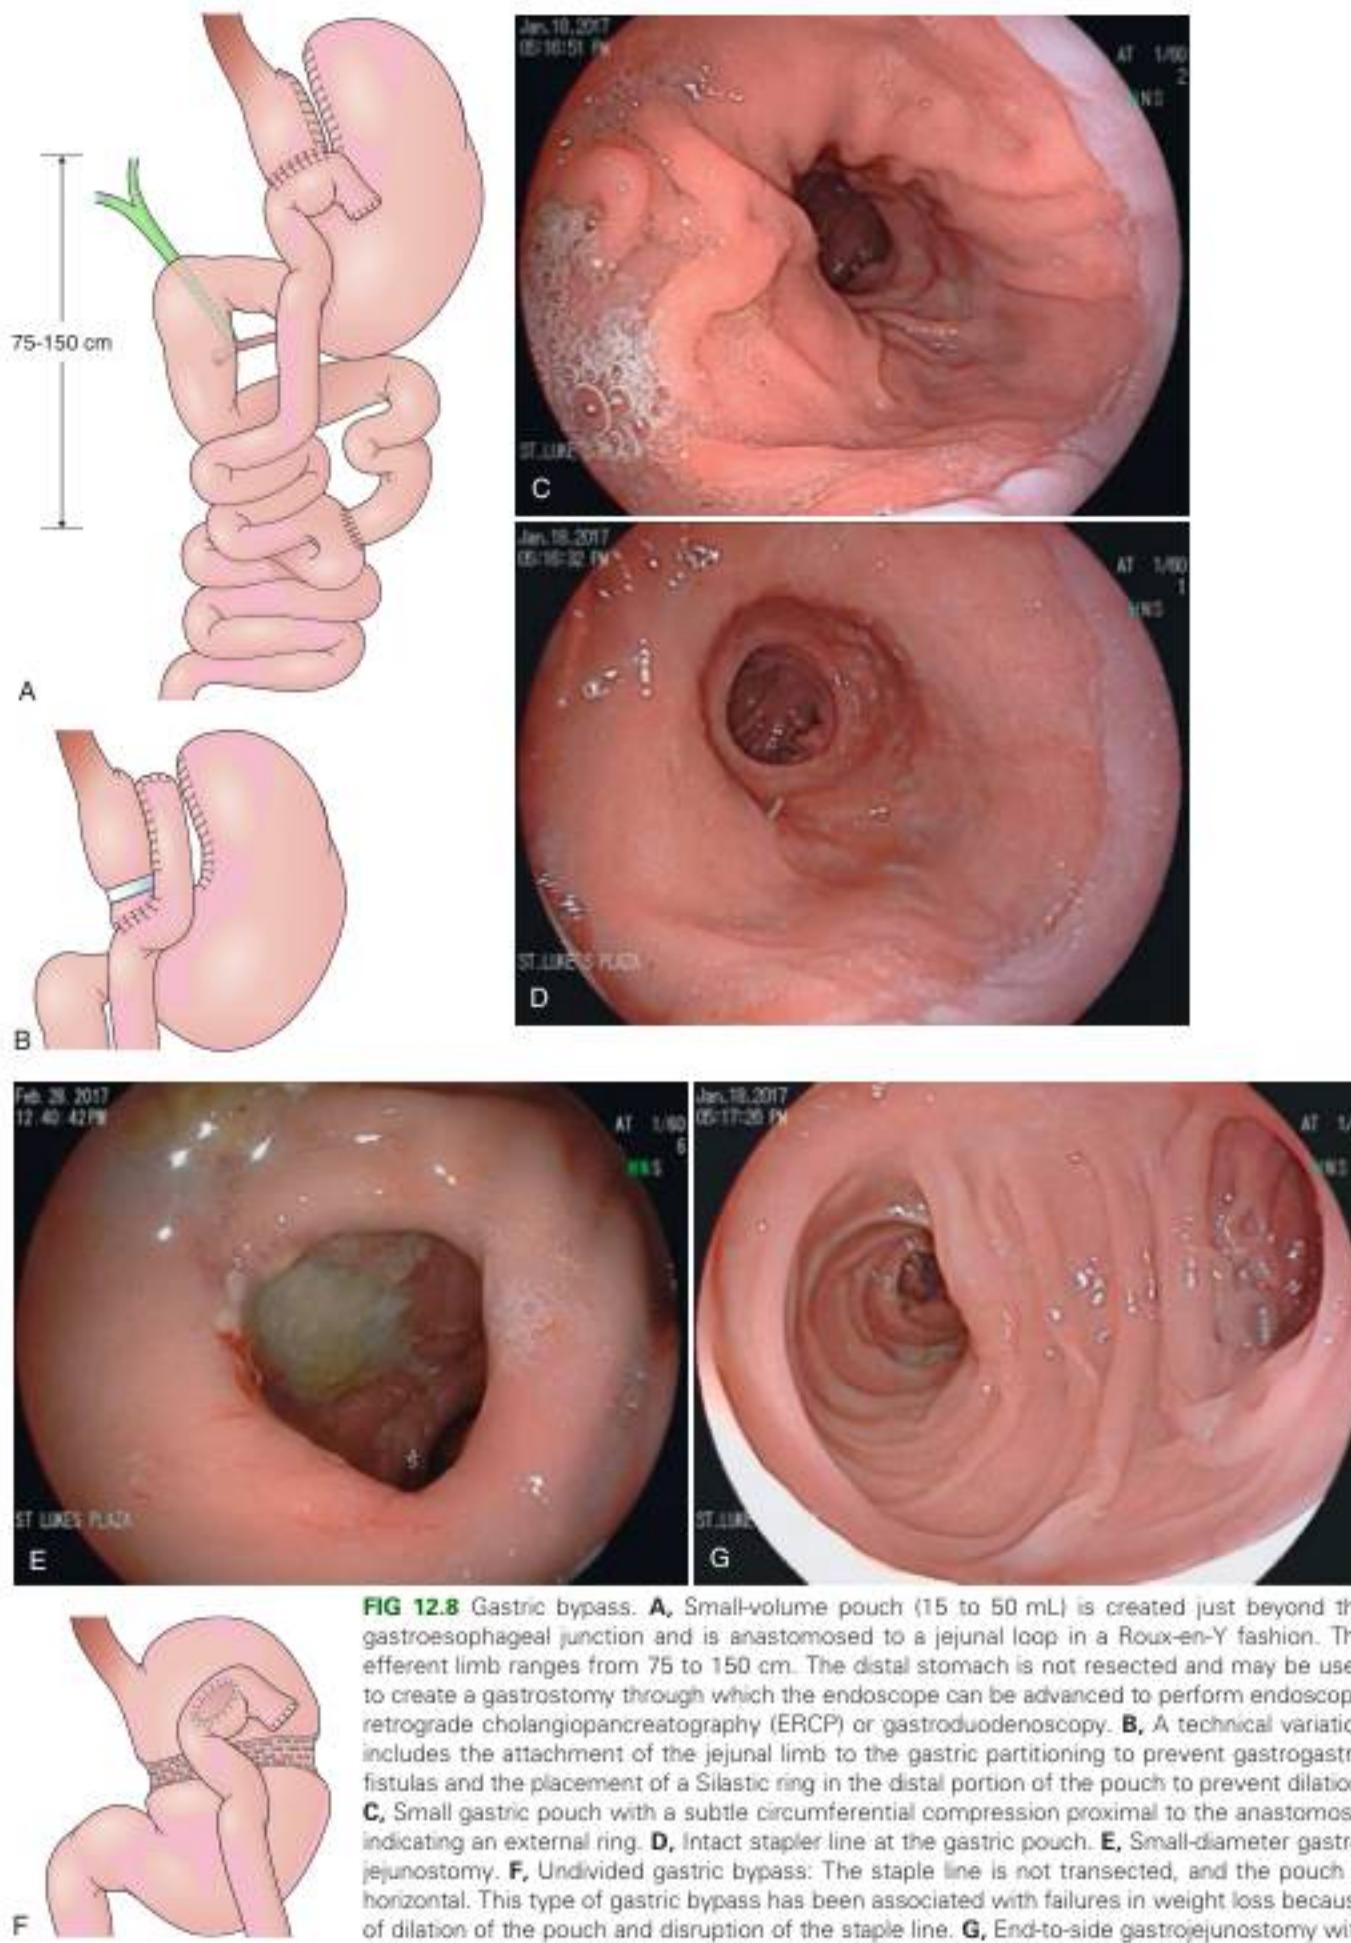

### Sleeve Gastrectomy

SG is a restrictive laparoscopic procedure in which the greater curvature is removed and a small gastric tube is left. Over the past decade, SG has emerged as a popular bariatric surgical approach. It was first introduced as the two-staged approach to duodenal switch (DS) or GB for the super obese patient.<sup>28</sup> The stand-alone SG has provided comparable results with the GB operation in regards to weight reduction and amelioration of obesity-related comorbidities.<sup>29–31</sup> Although GB is still the most common bariatric operation performed worldwide (45%), SG is now the most common bariatric operation performed in the United States/Canada (43%) and Asian/Pacific regions (49%) and the second most common worldwide (37%).<sup>32</sup>

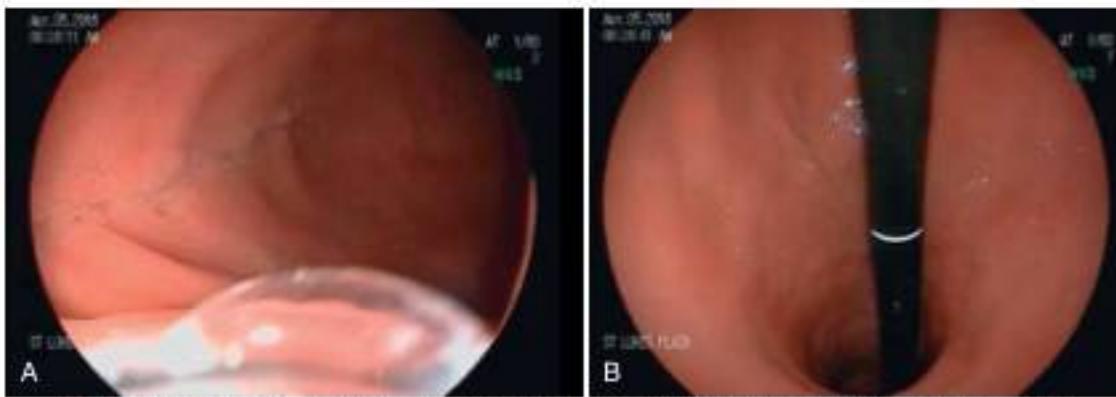

The endoscopic view after sleeve gastrectomy reveals a long, tubular stomach limited in expansion by a staple line that parallels the lesser curvature (Fig. 12.9). The DS procedure is often performed in conjunction with a SG, but also includes a duodenojejunostomy anastomosis visible just distal to an intact gastric pylorus. In the latter, the ampulla is thus not available for visualization or ERCP in a standard fashion.

### Vertical Banded Gastroplasty

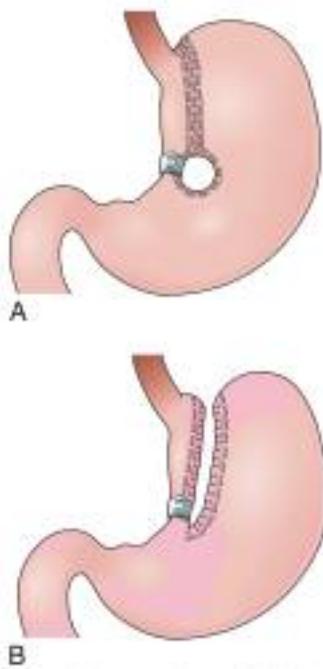

The initial gastroplasty procedure was inadequate in terms of weight loss and was refined by Mason into VBG. VBG is a purely restrictive procedure resulting from a search for a simpler operation compared with GB.<sup>33</sup> VBG involves the creation of a small pouch in the proximal stomach and the encirclement of the

**FIG 12.8** Gastric bypass. **A**, Small-volume pouch (15 to 50 mL) is created just beyond the gastroesophageal junction and is anastomosed to a jejunal loop in a Roux-en-Y fashion. The efferent limb ranges from 75 to 150 cm. The distal stomach is not resected and may be used to create a gastrostomy through which the endoscope can be advanced to perform endoscopic retrograde cholangiopancreatography (ERCP) or gastroduodenoscopy. **B**, A technical variation includes the attachment of the jejunal limb to the gastric partitioning to prevent gastrogastric fistulas and the placement of a Silastic ring in the distal portion of the pouch to prevent dilation. **C**, Small gastric pouch with a subtle circumferential compression proximal to the anastomosis indicating an external ring. **D**, Intact stapler line at the gastric pouch. **E**, Small-diameter gastrojejunostomy. **F**, Undivided gastric bypass: The staple line is not transected, and the pouch is horizontal. This type of gastric bypass has been associated with failures in weight loss because of dilation of the pouch and disruption of the staple line. **G**, End-to-side gastrojejunostomy with two openings. The right one is the efferent limb. The left one ends blindly.

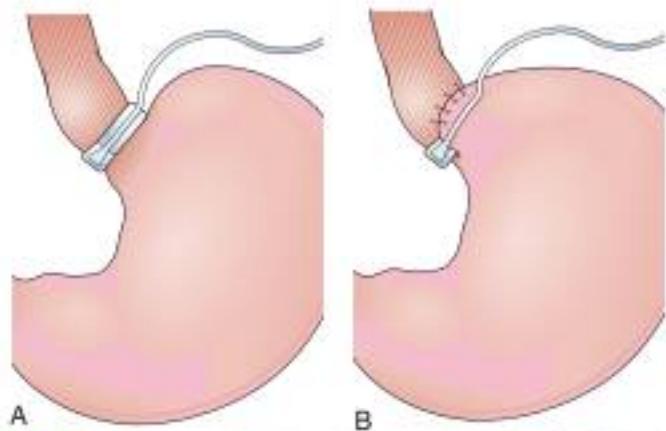

**FIG 12.9** Sleeve gastrectomy. **A**, Long tubular stomach limited in expansion by a suture line that parallels the lesser curvature. **B**, Retroflex view.

**FIG 12.10** Vertical banded gastroplasty. A 15-mL pouch is created at the angle of His, and the outlet channel is encircled by a circumferential band. **A**, Circular and linear staplers are used to create this uncut gastroplasty. **B**, The staple line may be divided, separating the two gastric parts to prevent gastrogastric fistula.

outlet channel to prevent dilation. The pouch is created along the lesser curvature with a stapled partition precisely at the angle of His to accommodate a volume of 15 mL or less. The outlet channel of the pouch is stabilized by the encirclement of a 5-cm circumference band or a Silastic ring (Fig. 12.10A). A technical variation includes dividing the stapled partition (see Fig. 12.10B).

Upper endoscopy in patients with intact VBG shows a small tubular pouch immediately after the esophagogastric junction with a narrow outlet channel that, once traversed, leads to the remaining distal stomach. Abnormal endoscopic findings include esophagitis, staple line dehiscence, food impaction, stenosis of the pouch outlet, and erosion of the gastric wall by the material used to encircle the outlet channel.<sup>103,104</sup> The remaining stomach,

**FIG 12.11** Laparoscopic adjustable gastric banding. **A**, A 15-mL pouch is created in the proximal stomach with a banding device. The device can be adjusted to narrow the opening to the distal stomach by percutaneous injection of fluids. **B**, A gastrogastric suture is placed anteriorly over the band to prevent gastric herniation.

duodenal bulb, and biliopancreatic ducts are readily accessible for endoscopy if the outlet channel permits passage of the endoscope. The outlet channel is ideally 11 mm wide and 15 mm long, and is amenable to endoscopic dilation in case of stenosis.

#### Laparoscopic Adjustable Gastric Banding

LAGB is the least invasive of the purely restrictive bariatric surgery procedure. LAGB was commonly performed in European countries and Australia, but now GB and SG account for almost 75% of bariatric surgery outside of the United States.<sup>103,105,106</sup> LAGB involves placing a band around the proximal stomach to create a 15-mL pouch without the need of resecting or stapling the stomach (Fig. 12.11A).

LAGB is now performed using a silicone material device that can be inflated with saline solution to adjust the gastric-pouch outflow. The inflatable part of the band device is connected by tubing to a reservoir, then implanted and secured to the abdominal fascia, which can be accessed via a needle.<sup>107</sup> There are unique long-term complications of LAGB, which include gastric prolapse, stomal obstruction, esophageal and gastric pouch dilation, gastric

erosion and necrosis, and access port problems. Use of a prosthetic device introduces additional potential problems of malfunction and infection.

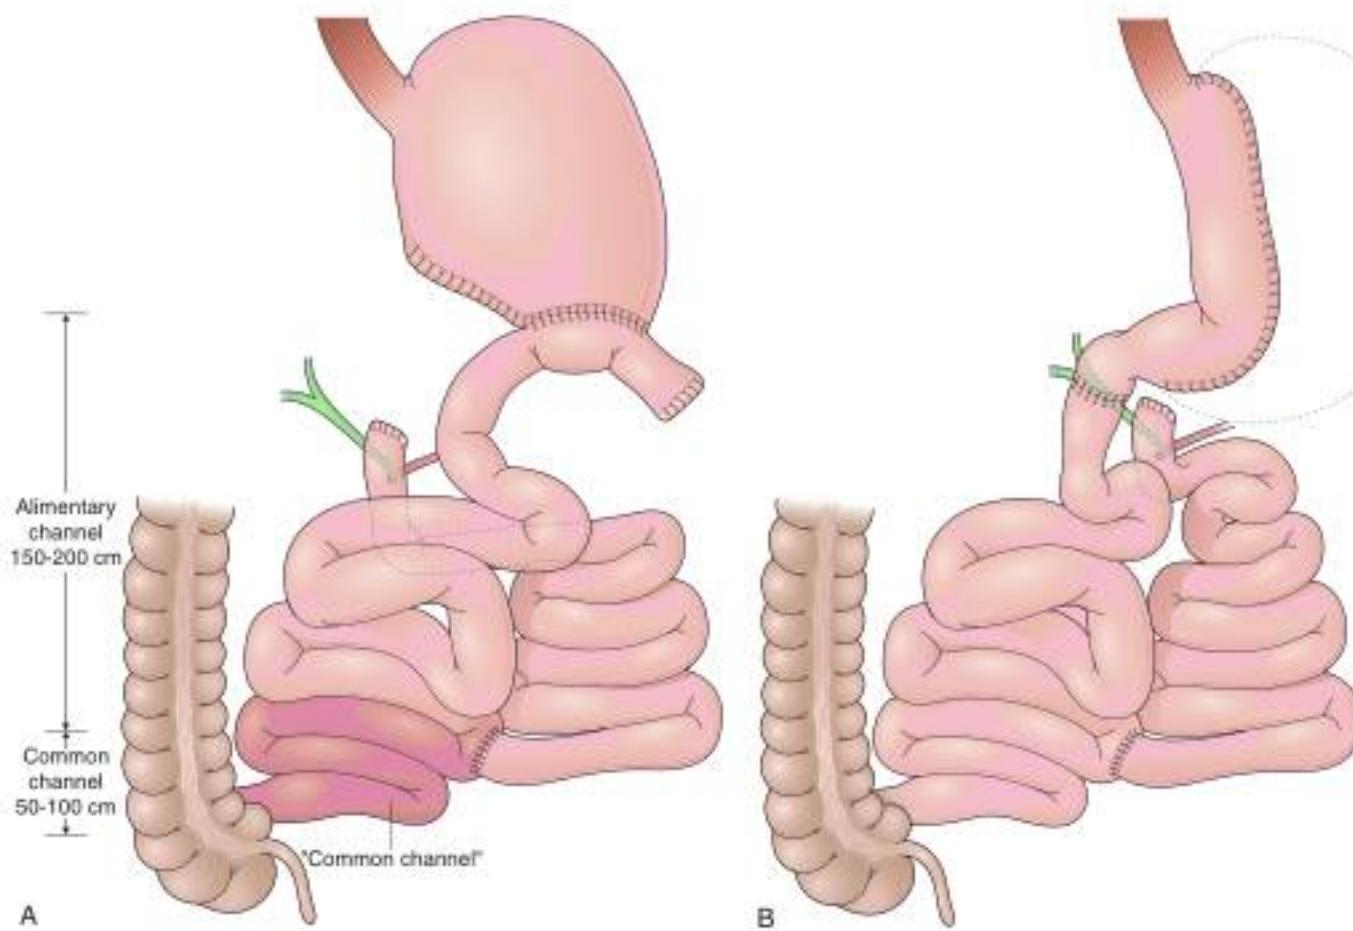

Upper endoscopy in a patient with LAGB shows a small gastric pouch at the level of the cardia with a narrow outlet channel that leads to the distal normal stomach. Esophageal dilation, esophagitis, gastric pouch dilation, gastric slippage, outlet channel stenosis, and gastric wall erosion by the band device are the most common abnormal findings observed after LAGB.<sup>108,109</sup> Occasionally, a marked gastric fold surrounding the pouch outlet channel can be observed in a retroflexed view within the distal stomach. This fold corresponds to the gastrogastric sutures placed anteriorly over the band device to decrease the risks of gastric herniation (see Fig. 12.11B). Similar to VBG, once the endoscope is advanced through the pouch-outlet channel, examination of the distal stomach, duodenum, and biliopancreatic ducts can be performed as in a regular endoscopy.

#### Biliopancreatic Diversion

Biliopancreatic diversion (BPD) is a malabsorptive procedure to delay contact between ingested food material, bile, and pancreatic juice.<sup>110</sup> BPD was first reported in 1979 by Scopinaro

et al and is also known as the Scopinaro procedure.<sup>111</sup> In BPD, the small bowel is divided, creating two limbs. The distal limb is anastomosed to the stomach, and the proximal limb is anastomosed to the ileum. After completion, the small bowel has a new anatomic configuration with three distinct channels: common, alimentary, and biliopancreatic (Fig. 12.12A). BPD requires no small bowel resection and does not leave a nonfunctional small bowel segment. The results of the procedure depend on the length of the channels, which are variable because of the individual patient characteristics and surgeon preferences. Typically, a 50-cm to 100-cm common channel and a 150-cm to 200-cm alimentary channel are created. The remaining small bowel constitutes the biliopancreatic channel.

The common channel length is the determinant for long-term weight maintenance and steatorrhea, and the total common alimentary channel is for the temporary mild short-gut syndrome. In addition, the stomach is altered via a partial resection or a GB to prevent peptic ulcer and to limit food intake. The gastric component of the BPD is easily accessible endoscopically, and the findings vary according to the procedure performed. Nevertheless, bile should never be observed, and peptic ulceration at the gastroenteroanastomosis and small bowel always should be

**FIG 12.12** Malabsorptive bariatric surgeries. **A**, Biliopancreatic diversion: a partial gastrectomy is reconstructed in a Roux-en-Y fashion with long afferent and efferent limbs (biliopancreatic and alimentary channels). Shadowed area represents the short length common channel (50 to 100 cm). **B**, Duodenal switch: a sleeve gastrectomy with preservation of the pylorus leads to a duodeno-jejunostomy rather than a gastrojejunostomy. Jejunal limbs are reconstructed as in a biliopancreatic diversion.

carefully investigated. If a partial gastrectomy was chosen, the stomach resembles a Roux-en-Y gastrectomy with a short proximal gastric pouch. A GB may appear as a vertical small gastric pouch or a horizontal pouch that includes the fundus. In a horizontal pouch, the anastomosis with the jejunum should be observed toward the greater curvature. A GB does not include stomach resection, leaving a nonfunctional distal gastric segment, and it can be divided or undivided.

Performing ERCP in a patient with BPD is nearly impossible per os because the endoscope has to be advanced all the way through the small bowel, except for the common channel, to reach the major papilla. Alternatives to access the major papilla are through a gastrostomy (surgical or radiologic) or through a disrupted staple line between the pouch and the stomach. These alternatives apply only for patients who had a GB because gastric resection precludes both options. Double-balloon enteroscopy has the potential to advance through the altered BPD anatomy and reach the major papilla.

#### Duodenal Switch

The DS procedure is a variation of BPD. This procedure includes an SG preserving the pylorus and anastomosis of the enteric limb end-to-end with the postpyloric duodenum (see Fig. 12.12B).<sup>130</sup> A lower prevalence of side effects has been reported for DS compared with BPD. The same principles described in regard to BPD apply to DS during the endoscopic evaluation, except that a duodenojejunostomy rather than a gastrojejunostomy is present.

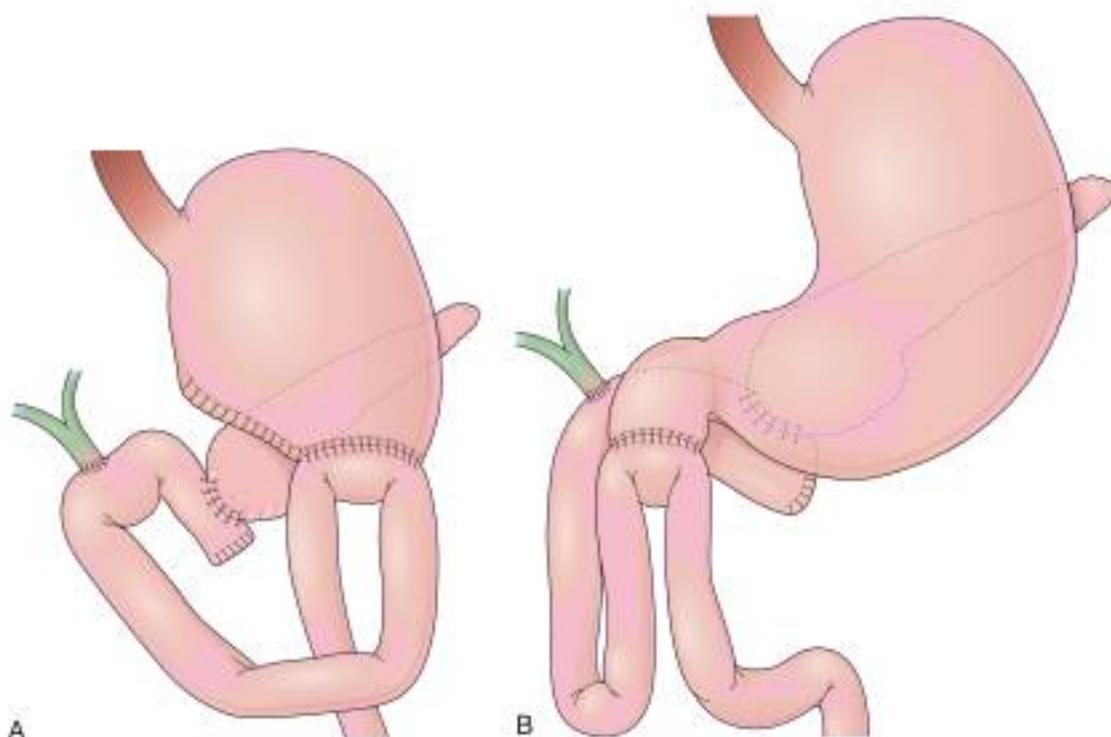

## OPERATIONS WITH ALTERATION OF THE PANCREATICOBILIARY ANATOMY

### Pancreaticoduodenectomy (Whipple Procedure)

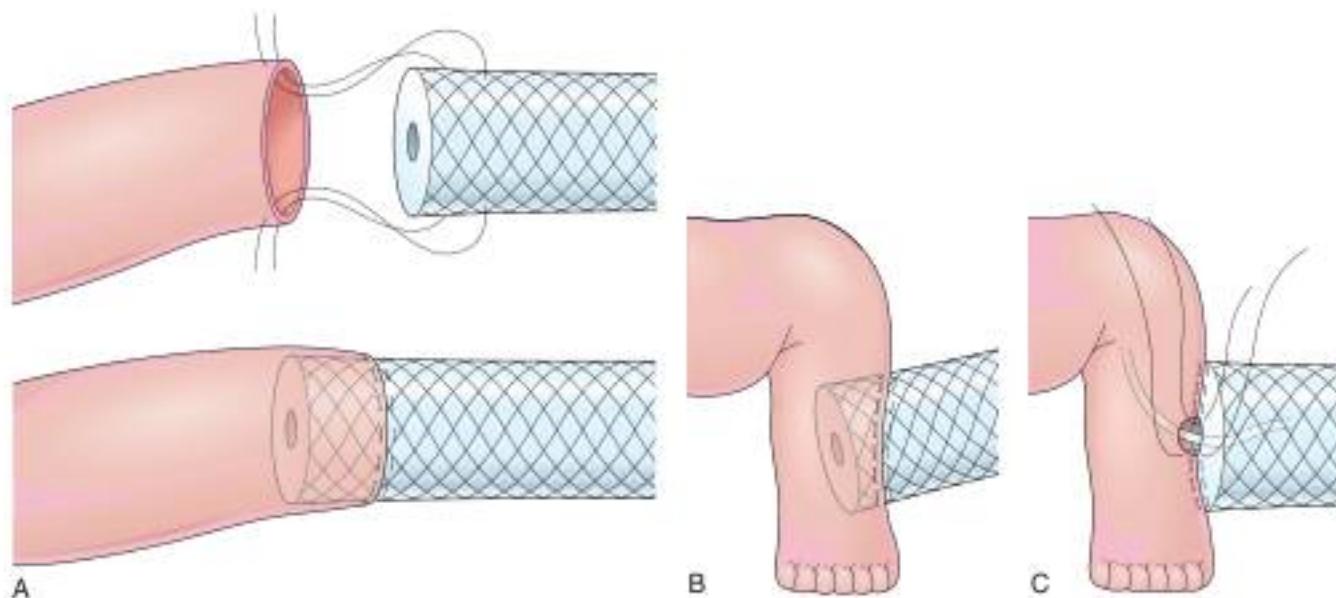

The Whipple procedure is performed to resect malignant or benign lesions in the head of the pancreas, distal bile duct, or in the second portion of the duodenum.<sup>112</sup> The extent of the resection classifies this procedure as classic or pylorus-preserving.

#### Classic Whipple Procedure

In the classic Whipple procedure, the gastric antrum, duodenum, head of the pancreas, and distal bile duct are resected. There are over 68 variations for reconstruction of the alimentary and pancreaticobiliary tract.<sup>113</sup> Currently, one well-accepted technique is to create all necessary anastomoses with a single limb of small bowel (Fig. 12.13A).<sup>114,115</sup> In this case, a side-to-side gastroenteroanastomosis is encountered endoscopically, usually oralis partialis and with the resection limited to the antrum. All the variations regarding orientation, position to the transverse colon, and stoma size described for the Billroth II gastroenteroanastomosis apply here. On entering the afferent limb, which may range from 40 to 60 cm and include a Braun procedure, the anastomosis with the biliary and pancreatic ducts can be identified. Sharp angulations resulting from fixation to adjacent organs may be encountered before reaching the blind end of the most proximal portion of the afferent limb, where the pancreaticojunostomy is found.

**FIG 12.13** Whipple operations. **A**, Classic Whipple: the distal stomach, head of the pancreas, distal biliary duct, and duodenum are resected. A single loop of jejunum is used for the anastomoses with the stomach and biliary and pancreatic ducts. A partial isoperistaltic gastroenteroanastomosis is shown. **B**, Pylorus-preserving Whipple: a duodenojejunostomy rather than a gastrojejunostomy is created in this procedure.

**FIG 12.14** Pancreaticojejunostomies. **A**, Terminoterminal dunking anastomosis in which the pancreas is invaginated into the jejunum. **B**, Terminolateral dunking anastomosis. **C**, Mucosa-to-mucosa pancreaticojejunostomy.

The pancreaticojejunostomy may be end-to-end or end-to-side. In either case, the pancreaticojejunostomy may also be a mucosa-to-mucosa or a "dunking" anastomosis.<sup>116</sup> A mucosa-to-mucosa anastomosis creates a small opening by suturing the pancreatic duct to the jejunal mucosa. The dunking anastomosis differs from the mucosa-to-mucosa anastomosis in that the pancreas is invaginated into the jejunum (Fig. 12.14). The opening of the pancreatic duct varies from a flat, small-diameter anastomosis (mucosa-to-mucosa) to a protuberant, sometimes downward-oriented anastomosis (lateral dunking), making the identification and cannulation of this duct technically challenging. The hepaticojejunostomy is located approximately 10 cm proximal to the pancreaticojejunostomy. It is always an end-to-side anastomosis located in the antimesenteric border of the limb, occasionally subtle or hidden by a fold.

#### Pylorus-Preserving Whipple Procedure

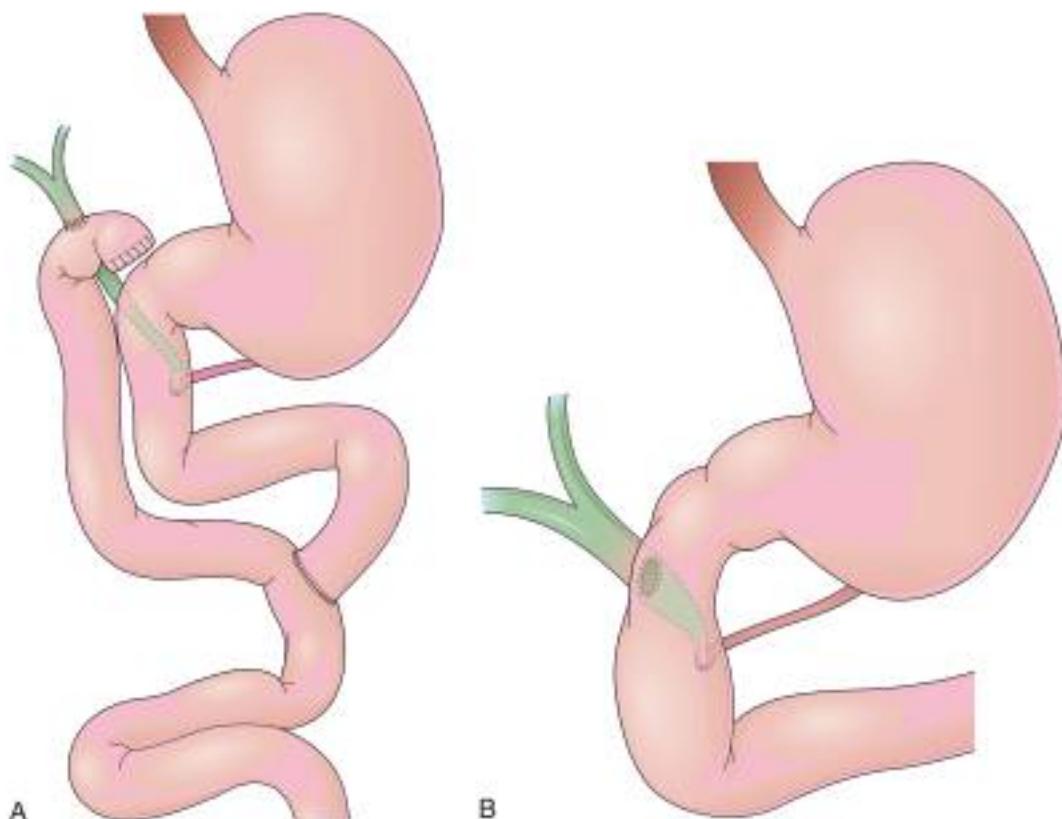

The pylorus-preserving Whipple procedure differs from the classic Whipple operation in that the stomach is not resected and a short segment of the proximal bulb remains to be anastomosed with the jejunum (see Fig. 12.13B).<sup>117</sup> This modification has proved to decrease the morbidity of pancreaticoduodenectomies, such as malnutrition due to the reduced volume of the stomach, without compromising the oncologic principles of the resection.<sup>118</sup> A duodenojejunostomy rather than a gastrojejunostomy is observed in patients with a pylorus-preserving Whipple procedure. After traversing a normal stomach and the pylorus, a two-opening, small-diameter anastomosis is identified in a short segment of bulb. Depending on the orientation of the reconstruction, the afferent limb is to the right (antiperistaltic) or to the left (isoperistaltic). Antecolic or retrocolic anastomosis can also be observed, creating variations on the length of the jejunal limb. Usually, a trial-and-error approach is necessary to define the afferent limb, in which the pancreatic and biliary anastomosis are performed as described for the classic Whipple procedure. In patients who have undergone either Whipple operation, the

biliary and pancreatic anastomosis may be reached with a side-viewing or a forward-viewing endoscope, owing to the relatively short afferent limb.

#### Roux-en-Y Hepaticojejunostomy

Anastomosis of the hepatic duct to a loop of jejunum without disturbing the gastroduodenal anatomy is usually performed for biliary disease or during liver transplantation when the native bile duct cannot be used to create a duct-to-duct anastomosis (e.g., in the setting of sclerosing cholangitis).<sup>119</sup> The hepaticojejunostomy is usually end-to-side, but side-to-side anastomosis can also be encountered (Fig. 12.15A). The anatomy of the stomach, duodenum, and pancreas is not altered, and endoscopic evaluation of these organs is similar to a nonoperated stomach. If the bile duct must be accessed, the endoscope has to be advanced through a normal stomach and duodenum before reaching the jeunojejunostomy that leads to a Roux-en-Y limb with the hepaticojejunostomy. Long-length endoscopes are usually necessary, and in most cases balloon enteroscopy systems employing an overtube are now used.<sup>120–122</sup>

In contrast to the anatomy after a Roux-en-Y gastrectomy, the duodenojejunial limb merges into the small bowel rather than merging with a loop of small bowel. At the level of the jeunojejunostomy, three lumens (side-to-side) or two lumens (end-to-side) can be observed, depending on the reconstruction (see Fig. 12.5E). One lumen leads to the distal jejunum, and the other leads to the limb that contains the hepaticojejunostomy. The third lumen (only if side-to-side) observed along the initial limb occupied by the endoscope ends blindly just beyond the anastomosis. A trial-and-error approach to the first two limbs reveals the one with the hepaticojejunostomy. The end-to-side hepaticojejunostomy is similar to the one described in the Whipple procedure except that here the location is closer to the blind end of the limb. In contrast to the end-to-side hepaticojejunostomy, the side-to-side hepaticojejunostomy preserves the access to the biliary ducts through the major papilla if the distal common

**FIG 12.15** Bilioenteric anastomoses. **A**, Roux-en-Y hepaticojejunostomy: the bile duct is anastomosed to a limb of jejunum in a lateral or terminal fashion. A side-to-side anastomosis preserves cannulation of the intrahepatic ducts through the papilla if no obstruction is present. The pancreatic duct remains accessible through the second portion of the duodenum. **B**, Choledochoduodenostomy: usually a side-to-side anastomosis is accessible on the second portion of the duodenum. The distal bile duct may be filled with residual enteric contents leading to the sump syndrome.

bile duct is not obstructed. In this case, a cholangiogram can be obtained with the aid of an occlusion balloon inflated proximal to the hepaticojejunostomy, avoiding the demanding insertion of the endoscope through the Roux-en-Y limb. Air within the intrahepatic ducts is common in bilioenteric anastomosis and may be useful to evaluate patients in whom the hepaticojejunostomy is not reachable with the endoscope (air cholangiogram).<sup>4,125</sup>

### Choledochoduodenostomy

Choledochoduodenostomy is the anastomosis of the bile duct to the second portion of the duodenum, usually performed in a side-to-side fashion (see Fig. 12.15B). Endoscopically, after traversing the pylorus, the choledochoduodenostomy is found proximal to the major papilla. The anastomosis may be sufficiently wide to allow visualization and partial intubation of the extrahepatic ducts. A side-to-side anastomosis has two lumens. One lumen leads to the proximal biliary tree, and the other leads to the distal common bile duct. Because there is no alimentary diversion from the anastomosis, food impaction may occur in the distal common bile duct causing the sump syndrome, which may require an ERCP.<sup>124</sup> Because the biliary duct can be accessed both through the major papilla and through the choledochoduodenostomy, a combination of accesses can be used to manipulate the different portions of the ducts, including anterograde cannulation of the papilla. The approach to the pancreatic duct is the same as for standard ERCP.

### INTRODUCTION

Safe performance of gastrointestinal endoscopic procedures requires extensive and high-quality training. Endoscopy skills have traditionally been taught within the clinical setting, in the form of a mentor-apprenticeship model in which novice endoscopists learn skills under the supervision of experienced preceptors. Concerns with regard to patient safety and training efficiency have prompted the endoscopy community to reconsider this training model. It is becoming increasingly less acceptable that endoscopic techniques are learned entirely in the clinical setting before trainees have shown some proficiency in their skills in a safe, controlled, simulated training environment.

Several factors have contributed to the shift toward incorporation of simulation into gastrointestinal endoscopy training. First, recent guidelines from endoscopy focused organizations such as the American Society for Gastrointestinal Endoscopy (ASGE)<sup>1</sup> have encouraged the use of simulation-based training, and it is now mandated by accreditation organizations in certain jurisdictions such as the United States.<sup>2,3</sup> Secondly, whereas the "ideal" training platform has traditionally been considered the patient, gastrointestinal endoscopy is uniquely challenging to teach in the clinical environment, as preceptors are required to relinquish complete control of the endoscope to allow trainees to learn the technique.<sup>4</sup> Clinical training also adds time to each procedure, which has implications with regard to capacity and economics.<sup>5</sup> Additionally, clinical demands and time restrictions often limit a preceptors' capacity to provide detailed instruction and feedback. Furthermore, training on patients occurs through chance encounters, which may limit exposure to particular pathologies. Finally, concern for patient comfort and safety can often impact

the learning experience and act to limit case availability and training exposure, especially for certain higher risk procedures such as endoscopic retrograde cholangiopancreatography (ERCP).

There are also a number of recognized benefits of endoscopic simulators that have helped drive their integration into training. Simulators provide learners with the opportunity to practice cognitive, technical, and integrative competencies related to endoscopy in a controlled environment.<sup>6,7</sup> Learners can build a framework of basic techniques through sustained deliberate practice in a setting where errors can be allowed to progress so trainees can learn from their mistakes without adverse consequences.<sup>8</sup> For novice learners, mastery of basic skills in a low-risk controlled environment, prior to performance on real patients, enables trainees to then focus on more complex skills once they progress to clinically-based training. Simulation also permits individualized learning, as cases can be adapted to a learner's unique needs and the nature and difficulty of the simulation tasks can be systematically varied over time to adapt to the skill level of the learner. Additionally, trainers do not have to juggle teaching and clinical demands and can instead focus solely on learners to provide a learner-centered educational experience and take full advantage of learning opportunities without distraction. Simulation can also be used to expose learners to patient pathophysiology or techniques (e.g., variceal banding) that might be rarely encountered in the clinical setting. In addition, the hands-on lab affords trainees with an optimal opportunity to develop critical communication skills needed to perform procedures that require coordination with one or more assistants. Finally, simulators can play a potential role in maintaining skills for practicing physicians who perform fewer endoscopic procedures or have taken a break in their training and/or practice.

### Abstract

Endoscopy skills have traditionally been taught within the clinical setting, in the form of a mentor-apprenticeship model in which novice endoscopists learn skills under direct supervision of experienced preceptors in the clinical setting. In recent decades, advances in the development of endoscopic simulators and concerns with regard to patient safety and training efficiency have prompted the endoscopy community to reconsider this training model. This has led to an increased use of gastrointestinal endoscopy simulation to enhance learner knowledge, skills, and attitudes and to provide opportunities for practice in a safe and controlled environment. Evidence to date suggests that simulation-based endoscopy training is effective and learning outcomes transfer to the clinical setting. Simulation, however, must be integrated into training and assessment in a thoughtful, purposeful, and evidence-based manner to maximize its benefit. This chapter outlines factors to consider in choosing an appropriate simulator for training and elaborates on the use of simulation to train endoscopic nontechnical skills. Additionally, instructional design features that can be applied to develop well-designed endoscopy simulation-based training curricula to enhance learning and optimize transfer of learner skills and behaviors to the clinical workplace are discussed. Finally, the potential use of simulation for assessment of endoscopic competence is outlined. Incorporation of these evidence-based educational strategies would advance the current state of endoscopic simulation and enhance the effectiveness of endoscopy training.

assessment  
clinical competence

Despite the shift towards simulation-based training and the potential benefits of simulation, a 2014 survey revealed that less than half of adult gastroenterology programs in the United States utilize simulation and it is mandated in only 15% of programs.<sup>3</sup> Across programs, simulation is being employed in a markedly heterogeneous fashion with regard to the manner in which it is integrated into training, the time spent on simulators, and the training tasks and types of simulators employed. Additionally, whereas program directors widely recognize the role that simulation can play with regard to assessment, no programs directors reported using simulation to assess endoscopic competence.<sup>3</sup>

As outlined in the ASGE's 2012 Preservation and Incorporation of Valuable Endoscopic Innovations (PIVI) report, the decision about whether to incorporate simulation technologies into endoscopy training must rely on data regarding the magnitude of training benefits, any cost savings resulting from accelerated learning, associated expenses, and training needs.<sup>1</sup> The use of simulation within a training curricula needs to be justified and outweigh the associated costs. The rationale for using simulation should be based on evidence with regard to the potential benefits for patients, trainees, preceptors, and training programs.<sup>1</sup>

With regard to upper endoscopy and colonoscopy, extensive systematic reviews on the topic have shown endoscopy simulation-based training to be beneficial for novice endoscopists in developing knowledge and technical skills in a safe and controlled environment, prior to clinical practice.<sup>10–12</sup> Existing randomized control trials (RCTs) have primarily shown benefit during the early phase of clinical work and potential benefit in shortening the learning curve to competency; however, a reduction in the learning curve of more than 25%, as proposed in the ASGE's PIVI report as a threshold for widespread adoption to their use, has yet to be demonstrated.<sup>1,10–14</sup> Additionally, diagnostic and therapeutic gastrointestinal endoscopy skills learned within the simulated setting have been shown to transfer to patient care.<sup>10–12,15</sup> To date, there is little evidence that patients benefit materially with regard to factors such as adverse events or satisfaction when a procedure is performed by a trainee with previous simulator experience. Potential cost and manpower reductions resulting from simulation training have also not been examined in depth.<sup>1</sup> Additionally, validated models for training more advanced therapeutic procedures such as polypectomy and stenting are lacking or sparse.

Whereas evidence to date suggests that simulation-based endoscopy training is effective and learning outcomes transfer to the clinical setting, simulation must be integrated into training and assessment in a thoughtful and purposeful manner to maximize its benefit. This chapter will outline factors to consider in choosing an appropriate simulator for training, elaborate on the use of simulation to train endoscopic nontechnical skills, discuss instructional design features that can be used to enhance endoscopic training using simulators, and outline the potential use of simulation for assessment of endoscopic competence. The value of simulation for basic endoscopy training<sup>18–22,16</sup> and details of available simulator models for specific procedures<sup>17–20</sup> have been reviewed extensively elsewhere and will not be discussed in depth.

## CHOICE OF SIMULATORS IN THE TRAINING ENVIRONMENT

Traditionally educators have favored high-fidelity computerized simulators for teaching technical skills based on the assumption

that they provide the optimal context to prepare learners for the clinical environment.<sup>1,21</sup> However, this assumption is not based on empirical data. Over the past decade, the capabilities of endoscopic simulators have steadily expanded. Currently, there are a wide variety of simulators available to teach endoscopy and one's choice of simulator should be based on the educational and/or assessment goals, as well as cost, as opposed to technology. Effective use of simulation is highly dependent on a close match of educational goals with simulation tools.

The use of simulation to teach gastrointestinal endoscopy dates back to the 1960s.<sup>4</sup> In general, there are five types of endoscopic simulators: (1) inanimate static models or mechanical simulators, (2) virtual reality computer generated models, (3) ex vivo (explanted organ) animal models, (4) live animal models, and (4) hybrid simulations. Every training model has its advantages and disadvantages and is best suited to training specific tasks and levels of learners (Table 13.1). Inanimate static models or mechanical simulators are part-task trainers that generally involve performance of characteristic motor tasks with a real endoscope within an inanimate closed environment with realistic visual and motor requirements and haptic feedback.<sup>22–24</sup> They generally do not provide summative feedback like some computerized endoscopy simulators do; therefore, a mentor must be present to guide training. However, they are inexpensive, portable, and allow for deconstruction of specific tasks such as retroflexion, torque steering, and tip control. Virtual reality computerized simulators, which became commercially available in the 1990s, are advantageous in that many are capable of providing real-time feedback and a library of clinical cases with varying degrees of difficulty of anatomy and complexity of tasks.<sup>4</sup> Whereas the virtual reality computer simulators incorporate pathology recognition, the relative value of simulator training in this core component of competency, as compared to didactic resources (e.g., web-based atlases, lectures) in combination with mentored clinical endoscopy experience, has not yet been determined. Additionally, virtual reality simulators are costly and not easily portable. Ex vivo (explanted) models are fabricated from a combination of plastic parts and explanted animal organs which can be used to train specific tasks such as endoscopic mucosal resection (EMR), ERCP, or hemostasis techniques.<sup>15,19,23,26</sup> Live animal models (e.g., anesthetized porcine model) are the most realistic endoscopy simulators. Although the haptic feedback closely resembles human tissue, there are distinct differences with regard to wall thickness and organ orientation, resulting in a slightly different "feel."<sup>16,19</sup> Animal models in general are difficult to prepare and use. They require procurement of animals and/or animal organs, extensive preparation and disposal processes, use of animal-use endoscopes, and they cannot be used indefinitely.<sup>18,19</sup> Ex vivo models have the advantage of being easier to assemble, more affordable, and raising less ethical issues when compared to use of live animals; however, they have unfavorable tissue characteristics compared with vital tissue.<sup>19</sup> Due to the aforementioned limitations, many endoscopy training programs do not use these simulator models locally and they are most often employed at specially equipped regional or national training courses or meetings. Finally, hybrid simulation links a simulated patient (i.e., an actor) with a computer-driven virtual reality simulator or inanimate model in a simulated clinical environment. It is advantageous in that it allows learners to perform endoscopic procedures in a holistic clinical context without risk of causing harm. Additionally, multidisciplinary team members, such as an endoscopic nurse and/or anesthesiologist, can participate in scenarios to facilitate

**TABLE 13.1 The Role of Various Endoscopic Simulation Models for Training**

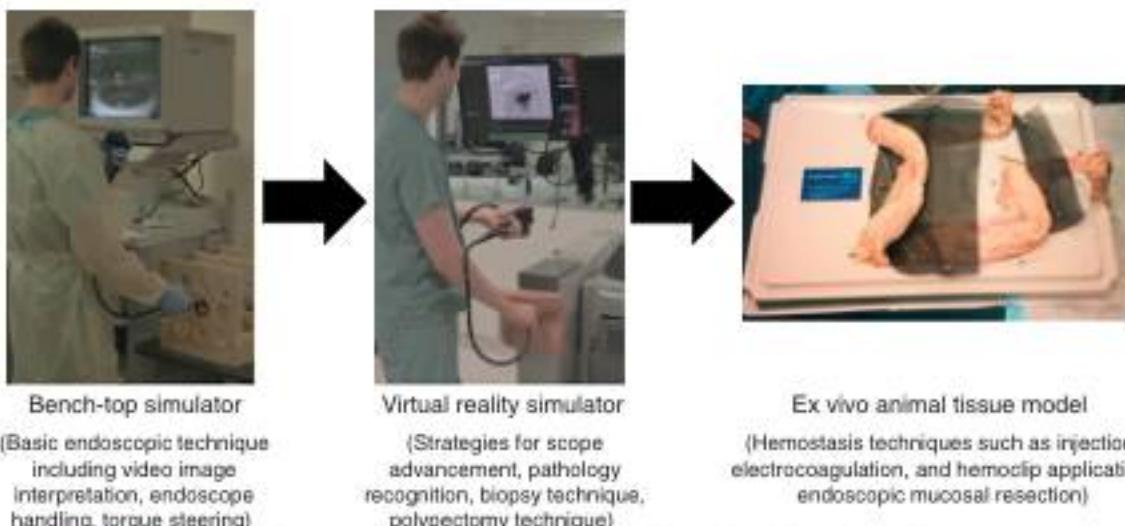

Simulator	Learner Level for a Given Task	Whole and/or Part-Task Training	Procedure(s)	Cost	Advantages	Disadvantages
Inanimate Static Models (Mechanical Simulators)	• Novice	• Part-task	Basic skills related to EGD, FS colonoscopy and ERCP	• Low	• Inexpensive • Portable • Minimal set-up • Task-specific • Allows for task-deconstruction • Real endoscope • +/- Variety of cases	• Cost • Feedback metrics not generated automatically
Virtual Reality Computer Generated Models	• Novice • Intermediate	• Part-task • Whole task	EGD, FS, colonoscopy, EUS, ERCP, sedation, hemostasis techniques, polypectomy, working with an endoscopic assistant	• High	• Automated feedback (although expert feedback superior) <sup>1</sup> • Variety of cases • Minimal set-up • Permits team training with assistant	• Expensive • Bulky / not portable • Real endoscope not used
Ex vivo Animal Models	• Novice • Intermediate • Advanced	• Part-task • Whole task	Hemostasis techniques, polypectomy, EMR, ESD, PEG tube insertion, ERCP, foreign body removal, stent placement, ablation techniques, suturing and defect closure, EUS/FNA, double balloon enteroscopy, working with an endoscopic assistant	• Medium	• Realistic • Allows for task-deconstruction • Real endoscope • Permits team training with assistant	• Requires specially equipped facilities • Cannot be used indefinitely • Somewhat resource intensive to set up • Feedback metrics not generated automatically
Live Animal Models	• Intermediate • Advanced	• Part-task • Whole task	ERCP, Hemostasis, EUS, ESD, manometry, working with an endoscopic assistant	• High	• Very realistic (including penile dilation and breathing movements) • Real endoscope • Permits team training with assistant • Ideal when bleeding control is a key skill (e.g., ESD)	• Expensive • Requires specially equipped facilities • Can't be used indefinitely • Resource intensive to set up • Ethical concerns • Feedback metrics not generated automatically
Hybrid Simulation	• Intermediate • Advanced • Endoscopic assistants • Anesthesia	• Whole task • Higher level integrative competencies (ENTSI)	ENTSI, working with an endoscopy team	• Medium	• Realistic • Ability to train higher-level integrative competencies <sup>1</sup> such as teamwork and communication	• Resource intensive to set up • Logistically can be hard to schedule multiple endoscopy team members for a single session

EGD, esophagogastrroduodenoscopy; EMR, endoscopic mucosal resection; ENTS, endoscopic non-technical skills; ERCP, endoscopic retrograde cholangiopancreatography; ESD, endoscopic submucosal dissection; EUS, endoscopic ultrasound; FNA, fine needle aspirate; FS, flexible sigmoidoscopy; PEG, percutaneous endoscopic gastrostomy.

training of integrative competencies related to endoscopy, such as situational awareness, professionalism, and communication. Integrative competencies are higher-level competencies required to perform an endoscopic procedure that complement an individual's technical skills and clinical knowledge to facilitate effective delivery of high-quality endoscopic care in varied contexts.<sup>4</sup> Integrative competencies include core skills, such as communication and clinical judgment, that allow individuals to integrate their knowledge and technical expertise to function effectively within a health care team, adapt to varied contexts, tolerate uncertainty, and ultimately provide safe and effective patient care.

As mentioned previously, educational goals, and not technology, should guide decisions about which simulator to use for

training and assessment. Certain simulators, such as virtual reality computer generated models and live animal models, are useful to teach performance of the procedure as a whole, whereas education in basic endoscopic procedural elements, such as video image interpretation, endoscope handling, and torque steering, can be delivered using simple and less expensive inanimate part-task trainers.<sup>12,13</sup> Becoming familiar with the endoscope and learning a procedure at the same time creates increased cognitive work load and slows skills acquisition.<sup>17</sup> Pretraining on a mechanical simulator until a certain level of proficiency is reached may help shorten the learning curve and better protect patients. Part-task simulators (including mechanical and ex vivo models) are useful to teach and/or reinforce particular skill sets or components of the procedure, such as polypectomy or bleeding

**FIG 13.1** An example progressive endoscopic simulation-based curriculum where learners proceed to training at progressively increasing levels of difficulty over time and simulator models are matched to the task.

control, as they deconstruct the skill set, allowing the learner to focus on the task at hand. Finally, more complex clinical events and behaviors, such as team training, benefit from use of more sophisticated hybrid simulations which involve use of inanimate or computerized simulators in conjunction with simulated patients (see the section entitled, Simulation to Train Endoscopic Non-technical Skills).

In deciding which simulator one should use for a given training goal or stage of training, one should consider both the capabilities of the simulator itself and the training program that will be used to support the model. Simulators can be used to teach and/or reinforce multiple training tasks depending on how they are integrated within a curriculum. Ultimately, the choice of simulator(s) must reflect the desired educational goals. We propose a three-stage framework for endoscopy simulation-based training that can be applied to help select simulators for a comprehensive endoscopy curriculum. The framework encompasses (1) task deconstruction using part-task trainers, followed by (2) use of simulators suited to whole procedural training and finally, (3) use of hybrid simulation to train higher-level integrative competencies related to endoscopic nontechnical skills.<sup>6,7</sup> This framework is theoretically in line with a progressive model of simulation-based training which is outlined in the following section. As mentioned previously, the utility of various simulators for specific training tasks is detailed in Table 13.1.

### Progressive Model of Simulation-Based Training

Progressive learning, which involves planned and gradual increases in the difficulty or complexity of simulation-based tasks as learners' abilities improve, can be used by educators to guide selection of simulators for educational programs.<sup>18,19</sup> In this way instruction is matched to the learner's developmental level and simulators are chosen based on their ability to train a specific task. Range of task difficulty can be varied longitudinally across a curriculum or within a single session. An example curriculum for endoscopy that is based on the progressive model of simulation-based training could start trainees on a low-fidelity, bench-top colonoscopy simulator<sup>20</sup> which is ideal to teach basic endoscopic skills with regard to interpretation of the video image,

endoscope handling, and torque steering (Fig. 13.1). A virtual reality simulator could then be used to teach learners various strategies for endoscope advancement (e.g., loop reduction, patient position change), pathology recognition, and basic biopsy and polypectomy technique. Subsequently, ex vivo animal tissue models could be used to train more advanced techniques such as EMR, or hemostasis skills including injection, electrocoagulation, and hemoclip application. This model of progressive simulation-based training has been used within the field of aviation with success.<sup>21</sup> In aviation training, as the situations grow more complex, trainees are increasingly required to troubleshoot difficult and unexpected situations. By analogy, particularly with the ex vivo models and hybrid simulation, and to an extent with difficult anatomy cases on the virtual reality simulator, progressive challenges can be created and trainees may be tasked to manage an unplanned adverse event in the controlled environment of the hands-on lab.

A recent RCT by Grover et al (2017)<sup>22</sup> within the field of gastrointestinal endoscopy has shown that a progressive simulation-based training curriculum that involves a deliberate transition from low to high task complexity and task difficulty improves colonoscopy skill acquisition and transfer to the clinical setting, compared to a curriculum utilizing high-fidelity simulation in isolation. It is thought that progressive simulation-based training is effective as task difficulty is adapted to align with the current skill of the learner, thus allowing learners to be optimally challenged as their skills improve; this is a factor known to enhance learning and promote task engagement.<sup>23</sup> As learners progress through training they can build upon previously attained competencies by engaging in activities of increasing difficulty without being cognitively overloaded. The aim is to train learners on progressively more challenging and difficult tasks that do not result in overwhelming the trainee in terms of cognitive load.

### SIMULATION TO TRAIN ENDOSCOPIC NONTECHNICAL SKILLS

Use of simulation enables learners to practice and receive feedback in a safe, learner-centered environment. Simulation can be used

to improve not only competence of endoscopic technical skills but also cognitive and integrative skills such as teamwork and decision-making.<sup>27</sup> Over the past decade there has been increasing recognition of the importance of endoscopic nontechnical skills (ENTS). In addition to the knowledge and technical skills required to perform endoscopy safely and proficiently, nontechnical skills play a central role in high-quality endoscopic practice. The vast majority of recommendations stemming from a report by the National Confidential Enquiry into Patient Outcomes and Death,<sup>28</sup> which investigated deaths occurring within 30 days of adult therapeutic gastrointestinal endoscopy procedures in the United Kingdom, highlight failings in nontechnical skills and behaviors such as communication, situational awareness, decision making, and teamwork, as opposed to technical skills. Nontechnical skills are an integral facet of competent endoscopic practice and an important contributor to patient safety and clinical outcomes.

Currently there is limited recognition, training or assessment of ENTS within endoscopy training programs. Training with regard to appropriate communication with an endoscopic assistant to coordinate techniques such as wire passage, injection, or polypectomy is often taught using ex vivo or virtual reality endoscopy simulator models. However, such training does not address the full breadth of nontechnical skills related to endoscopy, such as situation awareness. Hybrid simulation is a potential means of effectively training ENTS. Hybrid simulation is a term coined by Kneebone (2003)<sup>29</sup> to describe the process of attaching a simulator to a simulated patient. With regard to endoscopy, hybrid simulation involves a learner performing a procedure on an endoscopy simulator in a naturalistic setting (i.e., endoscopy suite), while interacting with an actor portraying a patient (i.e., a simulated or standardized patient) (Fig. 13.2). Multidisciplinary team members, such as an endoscopic nurse or anesthesiologist, can also be introduced into the scenarios. In this way, aspects of ENTS such as communication, decision making, leadership, teamwork, role clarity, coordination, shared goals, mutual respect, crisis management, and empathy can be taught during the simulations. Incorporation of debriefing that focuses on ENTS into team training allows team members to develop a shared mental model of the team's performance, reflect on their performance, and identify positive and negative aspects of performance to develop a plan for improvement and identify and mitigate causes of errors or near misses.<sup>30</sup> Recently published

studies by Grover et al (2015 and 2017)<sup>31,32</sup> support the use of a curriculum integrating hybrid simulation as a means to improve nontechnical skill acquisition in novice endoscopists and transfer of skills to the clinical environment. Salas et al (2008)<sup>33</sup> have identified evidenced-based principles for effective team training that can be integrated when designing endoscopy simulation-based team training sessions, including: (1) focusing team training on identified critical teamwork competencies; (2) emphasizing teamwork over task work; (3) ensuring training is relevant to the clinical environment; and (4) providing timely, descriptive and relative feedback, which is essential to correct and reinforce desired teamwork behaviors.

## INTEGRATING SIMULATORS INTO TRAINING

Health professions education has placed increased reliance on simulation in recent decades to enhance learner knowledge, skills, and attitudes, as well as to provide opportunities for practice in a safe and controlled environment. Development of any simulation-based training program should be evidence based, much like the practice of medicine. Integration of instructional design features known to enhance simulation-based instruction are required to optimize transfer of learner skills and behavior to the clinical workplace. Incorporation of these principles would advance the current state of endoscopic simulation-based training and enhance the effectiveness of endoscopy training. The following sections outline several educational principles that may be applied to develop well-designed endoscopy simulation-based training curricula to enhance learning.

### Curricular Integration

Thoughtful integration of simulation into an overarching curriculum is known to be an essential feature of its effective use.<sup>34</sup> Simulation is one of several teaching strategies available to educators to achieve learning outcomes. It is important to determine where simulation can be used most effectively within the context of a broader endoscopic curriculum by matching learning objectives to the educational method(s) best suited to teach those objectives. Maximal learning benefit is achieved by having an organized and systematic approach to the incorporation of simulation.<sup>35</sup> Simulation should ideally be a required component of standard adult and pediatric endoscopy training curricula and built into learner's regular training schedule to help facilitate learner engagement in deliberate practice. Additionally, core skills that are taught within the simulation-based environment should reflect the ways in which learner performance is assessed, as assessment is known to drive learning.<sup>36</sup> Currently, endoscopy curricula are lacking across many training programs.<sup>37</sup> There remains a need to develop a standardized endoscopy curriculum that integrates simulation in a thoughtful and purposeful manner to augment and reinforce clinical learning of technical, cognitive, and integrative (nontechnical) competencies related to endoscopy. The American Board of Surgery has recently developed the Flexible Endoscopy Curriculum as part of the Fundamentals of Endoscopic Surgery (FES) Program which focuses on equipping surgical residents with the knowledge and technical skill to be a surgical endoscopist.<sup>38,39</sup> This effort, which was sparked by limited numbers of clinical cases available for surgical residents to complete under direct expert supervision, is a first step in the generation of a milestone-based curriculum that includes both didactic and hands-on simulator training. However, the curriculum only focuses on cognitive and technical

**FIG 13.2** Colonoscopy hybrid simulation scenario, including an endoscopy nurse and the combination of a virtual reality simulator with a standardized patient.

milestones and fails to include training with regard to higher-level integrative (nontechnical) competencies required to perform endoscopic procedures safely and effectively, such as teamwork, decision making, and communication.<sup>47,48</sup> To date, validity evidence in support of the curriculum is lacking. Most important to the development of this and any future innovative curricula that integrate the use of simulators into training and assessment is the need to validate the results with evidence from objective performance data on real, unassisted procedures. For this purpose, the ASGE's PIVI report criteria serve as a useful guide.

### Deliberate Practice

Deliberate practice, a term initially used by Ericsson (2004) in instructional science,<sup>42</sup> involves focused repetitive performance of intended skills, coupled with informative feedback that promotes monitoring and error correction to improve performance in a specific domain. Deliberate practice is more predictive of expert performance than experience or natural aptitude.<sup>43</sup> Simulation is important as it affords trainees opportunities for deliberate practice of rarer or higher risk endoscopic procedures, such as management of gastrointestinal bleeding, in a controlled, low-risk environment. For deliberate practice to be effective, there have to be multiple different simulation experiences which increase in levels of challenge. Additionally, it is reliant on keen observers who are skilled feedback providers.

### Mastery Learning

Reflective of the movement towards outcomes-based medical education, mastery learning is an instructional approach that requires learners to achieve a defined proficiency before proceeding to the next instructional objective.<sup>44</sup> The time needed to achieve a mastery standard will vary between learners. Simulation-based training in other domains, such as surgery, that incorporates mastery learning has been shown to significantly improve skills acquisition and improve patient outcomes.<sup>44</sup> Three small feasibility studies have examined use of mastery learning for colonoscopy on a virtual reality simulator, the results of which indicate potential benefit, although none have directly compared mastery-based learning with other simulation-based learning strategies.<sup>45-47</sup> Key features of simulation-based mastery training include a baseline assessment, clear learning objectives, defined minimal mastery standards that must be sequentially met, and educational activities focused on achievement of mastery objectives with concurrent formative assessment to enhance learning and gauge progress.<sup>48</sup> Challenges to implementing mastery learning principles include the development of clearly defined goals, defensible mastery standards, and complementary assessment instruments with strong validity and reliability evidence.<sup>47,48</sup> To date, this has not been done within the field of endoscopy. Additionally, instruction using a mastery model takes more time.

### Task Variability

Real endoscopy provides marked variation in terms of anatomy, pathology, and procedural difficulty. Therefore, it is important to introduce task variability during practice to ensure learners have opportunities to engage in practice of endoscopic skills that capture or represent a wide range of patients.<sup>49</sup> Additionally, research from the motor learning literature has shown that skill acquisition and long-term retention of skills is enhanced when task parameters (e.g., difficulty, pathology encountered) are variable during practice. Simulation-based training that incorporates task variability can also help promote adaptive expertise.

Experts are flexible in their thinking and performance and are able to adapt to change and create new approaches to adapt to unexpected and complex problems. Research from the laparoscopic surgery literature has shown that learners who are exposed to variability during simulation-based training have improved flexibility of trained skills as compared to those who did not encounter task variability.<sup>50</sup>

### Distributed Practice

Although distributed and massed practice schedules have not been directly compared for endoscopy, studies from the surgical domain indicate that best training results are obtained when training is scheduled as multiple short training sessions distributed over time, as opposed to one long block of training.<sup>51</sup> With distributed practice learners tend to have less mental fatigue and thus are able to devote more cognitive resources to learning.<sup>51</sup> Distributed practice also allows more time for memory consolidation and mental rehearsal; both are considered key factors in enhancing the performance of procedures.<sup>52</sup> Before each spaced practice session, learners have to retrieve key aspects of the skill being learned from their memory, resulting in deeper encoding. Additionally, learners forget information over time; therefore, they have to invest more cognitive effort into learning, with a resultant positive effect on long-term retention.<sup>51</sup> Distributed practice is especially important for complex skills that take a number of practice attempts to achieve a plateau in skill acquisition. A distributed practice schedule, however, is often logistically more complicated to implement and thus most skills courses are predominantly conducted using massed practice schedules. Varying the task load during a session can potentially help reduce the detrimental effects of mental fatigue.

### Performance Enhancing Feedback

Provision of constructive feedback is a cornerstone of effective training and is recognized as the most important feature of simulation-based training.<sup>53</sup> The power of feedback depends largely on the properties of the information given, the manner in which it is delivered, and the way it is interpreted. Instructional feedback is a key motivator for trainees and has been shown to provide a distinct advantage in the acquisition of endoscopy skills.<sup>54,55</sup> Mahmood et al (2004)<sup>54</sup> showed that there is no improvement in endoscopy skills acquisition in the simulated setting in the absence of feedback, and studies comparing instructor-derived feedback with simulator-generator feedback have shown a distinct advantage with regard to instructor-derived feedback.<sup>55</sup> Additionally, the results of Grover et al's (2015)<sup>56</sup> recent randomized controlled study support integration of endoscopy simulation into a structured curriculum incorporating instructional feedback as a means to augment technical, cognitive, and integrative skills acquisition, as compared with self-regulated learning on virtual reality simulators.

Feedback that is tied to prespecified objectives and is followed by correction of performance forms the basis for deliberate practice, an essential component of attainment of expertise.<sup>42,55</sup> Feedback should focus on simple, well-defined, and achievable points to avoid overburdening the trainee. Feedback should ideally be a two-way process between the trainer and learner that is delivered in a nonjudgmental manner and is based on observable actions and linked to specific suggestions for improvement.<sup>56,57</sup> Additionally, it should be constructive, focused on improvement, and should strive to foster the trainee's conscious understanding of the steps required for performance. Incorporation of problem

solving and active decision making, especially with more advanced trainees, serves to improve self-reflection and ultimately conscious competence.<sup>36</sup> This is achieved by focusing feedback discussions on critical challenges during the procedure, having the learner diagnose the problem, review potential options and decide, in consultation with the instructor, which option to try. Questioning on the part of the trainer encourages active engagement and reflection and encourages learners to think independently and weigh potential solutions rather than simply being informed of the best option.<sup>36</sup>

The simulated setting provides an ideal environment for feedback provision as learners can work through errors independently and feedback delivery can be structured to enhance learning without compromising patient safety. For example, Walsh et al (2009)<sup>37</sup> found that the timing of feedback provision is an important factor influencing skill acquisition in novice endoscopists in the simulated setting. Terminal feedback that is given at the end of completion of a simulated task is more effective in promoting endoscopy skills acquisition and retention of skills as compared with feedback that is given during task performance.<sup>37</sup> Constant feedback may lead learners to depend on the feedback for guidance such that a learners' performance declines when the feedback is withheld. Additionally, constant feedback may cognitively overload learners as they are required to focus their attention on listening to the feedback, rather than engaging in the cognitive processing essential for learning (schema acquisition and rule automation).<sup>37</sup> Provision of continuous feedback may also disrupt the concentration of trainers and ultimately impair feedback provision as the simultaneous tasks of observation and feedback provision may place excessive cognitive demands on the instructor. Terminal feedback permits time for learners to focus their cognitive efforts on problem solving around difficulties; this is a factor known to enhance learning. Concerns for patient safety do not permit the use of terminal feedback within the clinical setting, pointing to the idea that simulation technology allows educators to use strategies known to enhance learning, such as terminal feedback, which are not possible to use when teaching in the clinical setting due to concerns for patient safety.

With regard to feedback interpretation, the perceived credibility of the feedback provider influences feedback effectiveness,<sup>38–41</sup> thus supporting the use of instructors with expertise in endoscopy and an awareness of principles of adult education. Additionally, feedback incorporating some objective indicators of performance increases the perceived credibility of the content of the feedback and likelihood that it is accepted. This supports the use of video to demonstrate errors or incorporation of simulator-generated metrics or validated assessment tools into feedback provision. Additionally, formative endoscopy assessment tools, such as the Gastrointestinal Endoscopy Competency Assessment Tool (GiECAT),<sup>42</sup> the Mayo Colonoscopy Skills Assessment Tool (MCSAT),<sup>43</sup> or the Assessment of Competency in Endoscopy (ACE) tool<sup>44</sup> can be used by endoscopy trainers to help guide feedback delivery as they help trainers identify areas the trainee needs to focus on to improve.

Debriefing after a simulation-based session allows learners the opportunity to engage in self-assessment, reflect on their performance, identify errors and successes, identify areas for development, and mitigate any lack of insight with the trainee. Debriefing discussions should be tied to the prespecified objectives for the training session. A useful guide for debriefing that is based on empirical evidence and educational theory is Rudolph

et al's (2008)<sup>45</sup> four-step model which includes (1) noting pertinent performance gaps related to predetermined objectives; (2) providing feedback that describes the gap(s); (3) investigating the basis for the gap(s) by exploring the frames (assumptions, goals, knowledge base) and emotions contributing to the current performance level; and (4) helping close the performance gap through discussion or targeted instruction about principles and skills relevant to performance. Every simulation-based training session should conclude with the generation of mutually agreed upon learning goals for future training episodes to continually reinforce and build upon existing competencies.

### Instructor Training

With regard to the effectiveness of simulation-based training, there is increasing recognition that the role of the instructor is a vital component to effective education and both endoscopy trainees and trainers believe more formal instruction on how to teach endoscopy to be beneficial.<sup>46,47</sup> The ability to teach endoscopy is an important skillset that can likely be enhanced with instruction.<sup>48</sup> Although research evaluating instructor training is lacking, it is increasingly recognized that endoscopy training should be ideally provided by individuals with the requisite skills and behaviors to teach endoscopy effectively and efficiently, including an awareness of adult education principles and best practices in procedural skills education. Observation and experience have shown that effective instruction is not easy or intuitive and that clinical experience is not a proxy for instructor effectiveness.<sup>49</sup> Endoscopy instructor courses aimed at teaching trainers essential components of an effective technical skills training session are increasingly being implemented across jurisdictions such as Canada<sup>50</sup> and the United States<sup>51</sup> and are now mandatory for adult gastroenterology endoscopy trainers in the United Kingdom.<sup>52,53</sup> These courses teach instructors evidence-based educational principles, such as use of performance enhancing feedback and standardized language, that can be applied by trainers to enhance learning in the clinical setting.<sup>50</sup> Although anecdotally very effective, with some evidence to show improvement in trainer confidence and skill,<sup>51</sup> the short- and long-term value and utility of these educational opportunities and their application to teaching in the simulated setting are currently unknown.

### SIMULATION-BASED ASSESSMENTS

An increased emphasis on quality, patient safety, learner-centeredness and social accountability has resulted in a paradigm shift across medical education from a process-based system that specifies the amount of time required to learn specified content to a competency-based system that is focused on describing and assessing outcomes that can be demonstrated in practice.<sup>54</sup> Competency-based medical education signifies a training process that results in documented achievement of the requisite knowledge, skills, attitudes, and behaviors for competent independent practice.<sup>55</sup> Reflective of this, endoscopy training programs are required to ensure that trainees are competent to perform endoscopic procedures safely, independently and competently upon the completion of training. Key to this need for quality assurance is the requirement for reliable, accurate and objective assessments of a trainee's skill.

High quality assessment is reliant on the existence of tools and measures that are both reliable and valid. Within the clinical setting, direct observation of procedural skills is the preferred

method to support ongoing skills assessment.<sup>7</sup> Direct observational assessment tools can be used during clinical training to monitor the learner's progress, guide performance-enhancing feedback, augment learning, identify learners who require more focused training, and ultimately to determine when a trainee has demonstrated sufficient competence to enter unsupervised practice.<sup>7</sup> With regard to colonoscopy, there are four direct observational assessment tools that have been developed and validated in a more systematic manner when compared with other published tools: The GiECAT,<sup>6,6,7,78</sup> the MCSAT,<sup>6,13</sup> the ACE<sup>6,16</sup> Colonoscopy Skills Assessment Tool, and the Joint Advisory Committee on GI Endoscopy's Direct Observation of Procedure (JAG-DOPS) Assessment Tool.<sup>77</sup> With regard to upper endoscopy, the ACE EGD Skills Assessment Tool<sup>79</sup> has been published, but studies evaluating its evidence of reliability and validity are lacking. An assessment tool with strong evidence of reliability and validity also exists for polypectomy, the Direct Observation of Polypectomy Skills (DOPyS) tool.<sup>78-81</sup> Rigorously developed direct observational clinical assessment tools, such as the aforementioned examples, are also useful with regard to simulation-based training, as they can help trainers pinpoint specific deficiencies that may be amenable to training on simulators. Additionally, psychometrically sound clinical assessment tools play an important role in the effort to develop and validate alternative assessment methods using simulators, as simulator-based assessment tools should be predictive of independently defined minimal competence parameters such as those generated by high-quality, direct, observational assessment tools.<sup>1</sup>

Simulation-based assessments are appealing to educators as they offer a proxy for clinical observations, thus enabling assessment at the "shows how" level of Miller's (1990)<sup>82</sup> pyramid. They are advantageous in that they are capable of providing assessments in a controlled environment that are less subject to assessor bias. Additionally, they are capable of delivering standardized, highly reproducible assessment scenarios across trainees (i.e., simulation is capable of eliminating variability due to pathology and/or anatomy) and learners at all stages of training can carry out assessment tasks independently on simulators in a risk-free environment, thus mitigating concerns for patient safety. Furthermore, simulation can be used to assess integrative competencies such as communication within immersive team-based scenarios.<sup>83</sup> For example, through use of an Integrated Procedural Performance Instrument (IPPI) format assessment scenario, initially described by Kneebone (2003),<sup>73</sup> during which participants are assessed performing a procedure on a endoscopy simulator in a naturalistic setting while interacting with team members (e.g., endoscopic nurse, anesthesiologist) and a standardized patient (i.e., a hybrid simulation as described previously).

Whereas simulation-based assessment has many potential advantages, what remains a challenge for the field of simulation is the development of models capable of providing accurate and reliable skills assessment. Prior to implementation of simulation-based assessment, tools for measuring endoscopy skills within the simulated environment must demonstrate acceptable evidence of reliability and validity. Currently, performance during an endoscopy simulation-based assessment is generally assessed by one of three means: virtual reality simulator metrics, motion analysis, and direct observational assessment tools.<sup>82</sup>

### Simulator Generated Performance Metrics

Virtual reality endoscopy simulators typically provide immediate and automatic assessment by generating computer measured

metrics of "performance" such as percentage of mucosa visualized, time to reach the cecum, and patient discomfort during the simulated procedure.<sup>83</sup> Simulator-derived metrics are advantageous in that they are objective and assessments can potentially be completed in the absence of an experienced endoscopist. A number of studies have been carried out to validate these metrics for various commercially available virtual reality colonoscopy simulators.<sup>1,4,84-86</sup> However, research assessing the validity of such metrics has yet to demonstrate that they are capable of meaningfully discriminating between endoscopists across varying levels of skill.<sup>1,4,78,84-85</sup> A reason for this limitation in some cases has been the observation that many of the modules are not difficult enough to perform to allow for such graded skill differentiation. Additionally, two studies of moderate quality which compared simulated and live performance ratings using poor quality direct observational assessment tools revealed that these metrics do not correlate with performance scores assigned by blinded expert endoscopists.<sup>86,87</sup> Furthermore, the use of computerized simulators for assessment purposes is often cost-prohibitive.

Virtual reality endoscopic simulation has recently been integrated into the board certification process for general surgery in the United States through the FES program. Modeled after the validated Fundamentals of Laparoscopic Surgery,<sup>98-100</sup> the FES program consists of web-based didactic material, a written examination to assess cognitive aspects of endoscopy, and a hands-on skill test on a virtual reality simulator. The FES performance-based manual skills assessment consists of five simulation-based tasks designed to assess fundamental endoscopy-related technical skills.<sup>101</sup> Although the assessment has good test-retest reliability (intraclass correlation coefficient [ICC] = 0.85), scores correlated only modestly with real-life colonoscopy performance ( $r = 0.78$ ) as assessed using the Global Assessment of Gastrointestinal Endoscopic Skills—Colonoscopy (GAGES-C)<sup>102,103</sup>; the GAGES-C is a direct observational assessment tool with moderate quality validity evidence that only assesses the technical aspects of endoscopic competence.<sup>7</sup> Proper validation of the FES or any other simulator-based assessment will require use of a clinical assessment tool with strong evidence of validity and reliability that incorporates cognitive and integrative components of endoscopic competence, as well as technical competencies, such as the previously mentioned GiECAT,<sup>6,6,7,78</sup> MCSAT,<sup>6,13</sup> ACE,<sup>79</sup> or JAG-DOPS<sup>77</sup> assessment tools, or from actual objective clinical outcome data. Additionally, assessors were not blinded with regard to the endoscopist's skill level.<sup>104</sup> Whereas this is a promising first step in the application of endoscopic simulation-based assessment, further research is required to determine whether a passing FES score is a reliable and valid marker of competence in performing clinical endoscopic procedures. In line with ASGE's PIVI report, it is recommended that simulator-based assessment tools must be procedure-specific and predictive of independently defined minimal competence parameters from real procedures with a kappa value of at least 0.70 for high-stakes assessment.<sup>1</sup>

Performance metrics derived from tasks performed on low-fidelity, part-task endoscopy simulators (e.g., precision, speed) are also being studied as a means to assess technical skills.<sup>23,105</sup> In particular, the Thompson Endoscopic Skills Trainer (TEST), which was developed to emphasize fundamental endoscopic technical skills for basic maneuvers including retroflexion, tip deflection, torque, polypectomy, navigation, and loop reduction, has been shown to differentiate technical skill accurately among all training levels (construct validity).<sup>23,105</sup> Whereas low-cost

simulators, such as the TEST, potentially enable assessment of particular tasks (e.g., retroflexion, torque) that could be used to help track achievement of specific technical milestones during training; further validity evidence is required before they are adopted broadly, including studies to establish learning curves and to correlate use to the simulator with improved clinical aptitude.

For simulator-derived metrics to be useful for formative assessment, they must be able to discriminate between endoscopists with small differences in experience (discriminative validity) in a manner that allows educators to identify discrete areas of deficiency and provide specific feedback and remediation. This might also allow program directors to implement mastery learning principles, requiring trainees to reach sufficient proficiency on simulators prior to advancing to further training with regard to more complex and higher risk procedures such as ERCP or EMR. For summative high-stakes assessment such as credentialing, not only would simulator metrics be required to demonstrate excellent discriminative validity, they would also need to correlate closely with competency in performing live endoscopy procedures in a reproducible, accurate, and reliable manner, preferably with a kappa of 0.7 of better.<sup>105</sup>

### Motion Analysis

Motion analysis can also be used to assess endoscopic performance within the simulated setting. Assessments based on motion analysis aim to quantify procedural dexterity using parameters generated by motion tracking hardware and/or software that are extracted from movements of the hands and/or procedural instrument(s) (e.g., force applied, path length, instrument trajectory).<sup>106</sup> The advantage of assessments based on motion analysis is that they are objective. However, they only permit quantification of technical skills and they are reliant on hardware and/or software resources which can potentially interfere with procedural performance (e.g., motion tracking sensors on an endoscopist's hands), thus limiting their feasibility. Additionally, whereas motion analysis can objectively assess procedural dexterity, it does not assess the full range of competencies required to perform a colonoscopy. Furthermore, motion-analysis research to date has been limited<sup>107–111</sup> and further validity evidence of the technology and appropriate metrics is required prior to widespread implementation.

### Direct Observational Simulator Assessment Tools

Direct observational assessment tools rely on an external rater to observe and assess learners using predefined criteria that are based on an assessment framework. Such tools are advantageous, as compared with simulator-generated metrics and motion analysis, as they are capable of providing trainees with more specific feedback with regard to performance quality and areas requiring improvement. Additionally, they allow for assessment of cognitive and integrative aspects of endoscopic competence such as knowledge of accessories, clinical judgment, and communication. Furthermore, they potentially enable one to measure direct transfer of skills between the simulated and clinical environment. To date, however, there are limited data examining reliability and validity evidence of a direct observational tool for simulated endoscopy.<sup>112,106,107,112,113</sup> Direct observation tools that have been assessed to date in the simulated setting lack the discriminative power to assess performance and determine competence in actual clinical performance. Further work is required to assess the psychometric properties of a comprehensive

observational assessment tool within both the simulated and clinical setting to enable measurement of transfer of skills between the two environments.

There are a number of compelling reasons to implement endoscopic simulation-based assessments; however, as mentioned previously, prior to widespread adoption further research is required to ensure these assessments can reliably distinguish between endoscopists with a range of endoscopic experience and predict competence in patient-based endoscopy.<sup>117</sup> Challenges remain with regard to the use of simulation for assessment, including the limited realism of simulators, lack of assessments with strong validity and reliability evidence, and the inability to control for potential simulator related behaviors, such as a "cavalier" attitude given trainees are aware that no real patients are at risk. Additional effort is needed to address these concerns, including improved assessment metrics and the development of assessments that utilize an adequate number of scenarios and raters to demonstrate acceptable reliability and validity. Further work is also needed to help determine where simulation is best placed within an overarching program of assessment and whether simulation-based skills assessment can be used to guide decisions with regard to progression of training (i.e., when to advance trainees' clinical responsibilities with regard to endoscopy) within a competency-based training model.

### LOOKING TO THE FUTURE

The past three decades have been characterized by a rapid expansion of simulation modalities designed to train individuals learning endoscopic procedures and a general acceptance of their use. However, there remains a need for integration of evidence-based principles to facilitate effectiveness of endoscopy simulation-based training, including curricular integration, deliberate practice, mastery learning, task variability, and performance enhancing feedback. Expert benchmarks of performance need to be established for various training tasks on simulators to create clearly defined metrics that can form the basis of proficiency-based training goals. And although goals are ideally determined in terms of mastery standards, training should ideally focus on provision of performance-enhancing feedback to augment learning. More efforts to develop and evaluate courses designed to train endoscopic instructors with regard to best practices for teaching in the simulated setting are also required to ensure widespread application of evidence-based educational principles known to enhance learning.

Much work also remains to clarify the optimal use of simulation-based training to supplement conventional endoscopy training. There is a paucity of comparative effectiveness studies (studies comparing one simulation modality with another active simulation-based intervention<sup>114</sup>) examining the effectiveness of instructional design features and best practice for selection of simulation modalities to train specific tasks. Furthermore, more work is needed to help elucidate how to best integrate simulation within a broader endoscopy curriculum to optimize safety, cost-effectiveness, learning, and skill transfer to the clinical setting. The timing, frequency, and duration of endoscopy simulation-based training required to optimize skill transfer to the clinical setting has yet to be fully elucidated. It also remains unknown whether ongoing work on simulators during patient-based clinical training has any complementary benefit, and if so, how much and for what specific techniques is the extra training worthwhile.

The major limiters with regard to implementation of endoscopic simulation into training remain cost and accessibility.<sup>9</sup> Advances in cloud-based technology and reductions in the cost of computing have yet to translate into far less expensive virtual reality simulators with processing centralized in the cloud via local dummy terminals. This obstacle continues to incentivize programs to try to do more with less costly static and ex vivo models. For broader adoption of simulation across training programs, affordable, validated, and easily accessible endoscopic simulators are required. Additionally, studies comparing the cost effectiveness of simulation as compared to other forms of training are needed, including examination of potential cost savings resulting from accelerated learning and the initial and ongoing expenses associated with simulation training.<sup>1</sup>

Based on current evidence, endoscopy simulation-based training has been shown to be useful in the early training phase in helping speed up the initial phase of the endoscopy learning curve and reduce patient burden.<sup>10,11</sup> To date, simulation has primarily been studied as a means to train novice endoscopists. Simulators have untapped potential to improve nontechnical aspects of endoscopic performance that has yet to be examined fully. Specifically, further studies are needed to assess simulation as a means to train broader integrative competencies related to the skill of endoscopy, such as teamwork and communication, and higher level competencies, such as crisis management, that require the integration of both technical and nontechnical skills for successful management.<sup>12</sup> Other potential expanded methods of using simulators that have yet to be explored can be drawn from the aviation industry, such as the use of simulation to help individuals learn how to troubleshoot difficult situations (e.g., perforation) that occur infrequently but must be mastered.<sup>13</sup>

The potential role of simulators as a means to train cognitive skills, in particular pathology recognition, also remains under-emphasized. Future work is required to determine how best to train in pathology recognition using simulators and how to optimally integrate other learning modalities, such as web-based pathology recognition e-learning modules, into an overarching simulation curriculum to maximize learning.

The role simulators can potentially play in maintaining skills related to endoscopy also remains unexplored, especially with regard to procedures where there may be insufficient clinical volume for adequate maintenance of skill. An evidence base also needs to be further established with respect to best practices in the use of simulation for training of more advanced endoscopic skills. It is important to continue to improve upon simulator models to allow for the deliberate practice of therapeutic interventions, such as polypectomy, injection techniques, hemostasis techniques, stent deployment, and closure of defects with clips.

In addition to training, simulation is increasingly being used as a tool for credentialing, licensing, and certification across disciplines.<sup>14</sup> With regard to gastrointestinal endoscopy, the field is still a long way from achieving such a goal. An important challenge for the endoscopy simulation field will be the development of models capable of providing accurate skills assessments that can reliably predict clinical performance at preestablished benchmarks of competency. Such assessments could be used during the course of training to help guide when trainees might advance to subsequent levels of clinical responsibilities, allowing them to perform more technically demanding procedures. Additionally, reliable and valid simulator-based assessments would be of enormous value as they would provide unbiased and reproducible measures for credentialing purposes and help ensure

patients that the individuals performing their endoscopy have been trained to sufficient minimum standards of quality.<sup>1</sup>

There remains a need to develop further high-quality procedure specific clinical assessment tools, such as the GiECAT,<sup>15</sup> MCSAT,<sup>16</sup> ACE,<sup>14</sup> and JAG-DOPS,<sup>17</sup> that possess strong validity and reliability evidence to establish learning curves and performance benchmarks for all endoscopic procedures against which simulator-based metrics can be validated. Once key, clinically relevant, metrics for a technique are identified, assessment tools based on these metrics need to be developed that are accurate, reliable, and capable of distinguishing individuals with a range of endoscopic experience. These tools should also accurately predict actual clinical performance and correlate with clinical performance benchmarks in prospective validation studies.<sup>1</sup> To achieve this goal, better tracking of longitudinal outcomes, such as cecal intubation and adenoma detection rates, is needed across procedures as a means to validate simulation-based assessments and help examine the long-term impact of simulator enhanced training. Finally, additional research is required to determine where simulation-based assessments are best placed within an overall program of assessment to maximally augment learning. Ultimately, improving the use of simulation for assessment purposes will greatly broaden the appeal and value of simulators to hospitals who are responsible for credentialing individuals to perform endoscopic procedures and aid in improving learner access to simulators and integration across training programs.

### INTRODUCTION

The annual incidence of upper gastrointestinal bleeding (UGIB) is 48 to 160 events per 100,000 adults in the United States, where it is the cause of approximately 300,000 hospital admissions per year.<sup>1,2</sup> In Europe, the annual incidence of UGIB in the general population ranges from 19.4<sup>3,4</sup> to 57.0<sup>5,6</sup> events per 100,000 individuals. There is no formal explanation for the breadth of the range between countries, although differences in health care systems and case recording capacities may be substantial.<sup>4,5</sup> Additional contributing factors may include alcohol intake and *H. pylori* prevalence.

In both North America and Europe, in a general practice setting, approximately 80%–90% of acute UGIB episodes have

a nonvariceal etiology with peptic ulcers and gastroduodenal erosions accounting for the majority of lesions.<sup>7,8</sup> UGIB-related mortality rates have decreased in the past two decades, but still range from 2% to 15%.<sup>9,10</sup> Two studies conducted in the United Kingdom highlighted that, despite a notable decrease in mortality in patients with UGIB from 1993 to 2007, mortality from peptic ulcer bleeding is still 10%–13%.<sup>7,9</sup>

This chapter discusses the various management principles of medical therapy in nonvariceal UGIB (NVUGIB) put forth by guidelines from the multidisciplinary international consensus group in 2010, the American College of Gastroenterology in 2012, and the European Society of Gastrointestinal Endoscopy in 2015.<sup>11,12</sup> When applicable, more recent evidence is included with a focus on randomized controlled trials (RCTs) and metaanalyses.

**Abstract**

This chapter discusses the diagnostic and management principles in nonvariceal upper gastrointestinal bleeding (NVUGIB) put forth by guidelines from the multidisciplinary international consensus group in 2010, the American College of Gastroenterology in 2012, and the European Society of Gastrointestinal Endoscopy in 2015. When applicable, more recent evidence is included with a focus on randomized controlled trials and metaanalyses. Each section of this chapter presents the most current evidence and provides recommendations for practice. This chapter focuses on providing an evidence-based approach to initial resuscitation, the role of blood transfusion, pre-endoscopic, endoscopic, and postendoscopic management for patients presenting with NVUGIB.

**Keywords**

risk stratification

Each section of this chapter presents the most current evidence and provides recommendations for practice. This chapter focuses on providing an evidence-based approach to initial resuscitation, the role of blood transfusion, preendoscopic, endoscopic, and postendoscopic management for patients presenting with NVUGIB.

## CLINICAL PRESENTATION

The presentation of GI bleeding is dependent on the site, volume, and rate of bleeding. The most common clinical presentation of UGIB, defined as a source proximal to the ligament of Treitz, includes either hematemesis or melena. Occasionally, the emesis can appear to resemble coffee-grounds, which can occur when older blood in the stomach is reduced by stomach acid. The appearance of melena (black, tarry, and foul-smelling stool) is caused by the degradation of blood as it passes through the small bowel and colon. Bleeding that originates from the small bowel or proximal colon can also present with melena. Importantly, a massive UGIB can manifest as hematochezia (bright red blood per rectum) since the rapid passage of blood through the GI tract does not have time to be degraded. Presentation with hematochezia accounts for approximately 10% of patients with NVUGIB and is more common in patients presenting with hemodynamic instability.<sup>6,13</sup>

## INITIAL EVALUATION

The immediate priority in management is to secure the patient's airway, and tend to breathing and circulation.<sup>14</sup> The patient should be placed in a monitored setting, at which point large-bore venous access should be established. Resuscitation should be initiated for patients with NVUGIB prior to any other procedure, and should include stabilization of the blood pressure with appropriate infusion of sufficient fluid volumes.<sup>15,16</sup> In the intensive care unit (ICU), saline or Ringer acetate is preferred to hydroxyethyl starch (HES), as HES has been shown to increase the need for renal-replacement therapy in ICU patients, and may increase severe bleeding.<sup>17</sup>

The primary objectives of resuscitation are to restore blood volume and to maintain adequate tissue perfusion, in the hope of preventing hypovolemic shock and ultimately death. No data suggest that any particular type of colloid solution is safer or more effective in patients needing volume replacement.<sup>18</sup> Certain patients will require resuscitation with blood products including red blood cells, platelets, and, rarely, clotting factors (e.g., fresh frozen plasma).

## LABORATORY DATA

Certain laboratory tests are required at initial presentation to guide resuscitation and to risk-stratify patients based on established scoring systems.<sup>19</sup> Initial blood work should include: hemoglobin level, platelet count, blood urea nitrogen, creatinine, prothrombin time, and partial thromboplastin time.<sup>20</sup> A type and screen or cross-match is indicated if transfusion is being considered. Other investigations including liver enzymes and liver function testing, cardiac enzyme testing, and an electrocardiogram are often performed to exclude potential confounding diagnoses or complicating conditions. Additional investigations can be guided by individual patient characteristics noted on history or physical examination.

## ROLE OF NASOGASTRIC ASPIRATE

The routine placement of a nasogastric tube (NGT) in patients presenting with NVUGIB remains controversial and is not recommended by current guidelines.<sup>2,12</sup> One 2013 retrospective study of 166 patients was able to predict active bleeding at endoscopy by combining NGT aspirate results with blood pressure and heart rate parameters.<sup>21</sup> Opinions vary as high-quality evidence is lacking to decide whether certain patients benefit from NGT aspiration and lavage to help aid in both diagnosing UGIB, as well as improving visualization during endoscopy.<sup>22–25</sup> Studies have failed to show any improvement in clinical outcomes attributable to the insertion of an NGT.<sup>26–28</sup> One study identified 520 patients with UGIB who had a documented nasogastric aspirate prior to endoscopy and found that a bloody aspirate was associated with high-risk lesions (odds ratio [OR] 4.82) although the negative predictive value was only 77.9%.<sup>22</sup> Importantly, a clear nasogastric aspirate reduced the likelihood to 0.15. There are, however, certain patients in whom the source of GI bleeding is unclear and who may benefit from placement of an NGT to confirm an upper GI source.<sup>29</sup> Current guidelines do not suggest routine use of NGT placement prior to endoscopy.<sup>11</sup>

## RISK STRATIFICATION

Several scoring systems have been created to risk-stratify patients presenting with NVUGIB.<sup>31–35</sup> Patients who are deemed high-risk may benefit from earlier and more aggressive treatments, including admission to the ICU and more rapid endoscopic evaluation.<sup>34–36</sup> Moreover, low-risk patients may be appropriate for outpatient management, which could be safe and more cost-effective.<sup>37–40</sup> Each scoring system has strengths and limitations that we will briefly outline hereafter. For detailed descriptions of the components of the most studied scores, see Table 14.1.

The Rockall score has been shown to accurately predict rebleeding and mortality rates for patients presenting with NVUGIB.<sup>41,42</sup> This scoring system incorporates clinical and endoscopic information to provide a total score for each patient. Multiple studies have validated the Rockall score and suggest that patients with a low score have a lower likelihood of rebleeding and mortality.<sup>43–45</sup> Specifically, a score of less than 3 predicts a rebleeding rate of approximately 5% and a mortality rate of 0%. The major limitation of the Rockall score is that endoscopy must be performed to calculate the total score, thus limiting its usefulness in preendoscopic risk stratification.

The Glasgow-Blatchford score (GBS) uses clinical data on presentation to determine whether a patient with NVUGIB will require a blood transfusion, endoscopic intervention, or surgery.<sup>46</sup> Several prospective studies have evaluated whether certain patients with low GBS scores can be discharged safely from the emergency department without immediate endoscopic evaluation.<sup>37,47,48</sup> One prospective, multicenter study found that patients presenting to the emergency department with a GBS score of 0 could be safely managed as outpatients because none of these patients returned to their index hospital with recurrent UGIB or death within 6 months.<sup>48</sup> More recently (2012), a metaanalysis found that a GBS score of 2 or more was 98% sensitive at identifying patients who require urgent evaluation.<sup>49</sup>

The AIMS65 score represents one of the most recently developed tools for risk-stratifying patients and may be superior to previous scoring systems with regards to predicting inpatient mortality.<sup>50</sup> Using only 5 clinical variables available at presentation,

**TABLE 14.1 Components of the AIMS65, Glasgow-Blatchford, and Rockall Scores**

AIMS65		GLASGOW-BLATCHFORD		ROCKALL	
Variable	Score	Variable	Score	Variable	Score
Albumin < 3.0 g/dL	1	Blood urea nitrogen (mg/dL)		Age	
INR > 1.5	1	≥ 6.5 to < 8.0	2	< 60	0
Altered Mental Status	1	≥ 8.0 to < 10.0	3	60 to 79	1
SBP ≤ 90 mm Hg	1	≥ 10.0 to < 25	4	> 80	2
Age > 65	1	≥ 25	6	Shock	
		Hemoglobin (g/dL): Men		No shock	0
		≥ 12.0 to < 13.0	1	Heart rate > 100	1
		≥ 10.0 to < 12.0	3	HR > 100, SBP < 100	2
		< 10.0	6	Comorbidity	
		Hemoglobin (g/dL): Women		Heart failure or IHD	2
		≥ 10.0 to < 12.0	1	Renal or liver failure or	3
		< 10.0	6	Metastatic cancer	
		Systolic BP (mm Hg)		Endoscopic Diagnosis	
		100 to 109	1	No lesion or MWT	0
		90 to 99	2	All other diagnoses	1
		< 90	3	Malignancy	2
		Other Variables		High-Risk Stigmata	
		Heart rate > 100	1	None or dark spot	0
		Melena at presentation	1	Active bleeding or clot or visible vessel	2
		Syncope	2		
		Hepatic disease	2		
		Heart failure	2		
Maximum Score	5	Maximum Score	23	Maximum Score	11

HR, heart rate; INR, international normalized ratio; MWT, Mallory-Weiss tear; SBP, systolic blood pressure; IHD, ischemic heart disease.

Data from Saltzman JR, Tabak YP, Hyett BH, et al. A simple risk score accurately predicts in-hospital mortality, length of stay, and cost in acute upper GI bleeding. *Gastrointest Endosc* 74(6):1215–1224, 2011.

it is more accurate at predicting mortality than the GBS score.<sup>51</sup> The AIMS65 score, however, was less accurate at predicting the need for blood transfusion than GBS score, and similar in predicting in-hospital rebleeding.<sup>52</sup>

Limitations of all three scores include disparate comparative study results, variations in performance based on study populations and (surprisingly) geographic regions, and the absence of true interventional trials assessing patient outcomes following the introduction of a score early on in patient management.<sup>53,54</sup>

## RED BLOOD CELL TRANSFUSION

The decision whether to transfuse red blood cells is based on the presenting hemoglobin level, hemodynamic status, patient comorbidities such as cardiac disease, and symptoms of anemia. A large Cochrane review put into question the usefulness of red blood cell transfusions in UGIB, demonstrating no overall survival benefit.<sup>55</sup>

A 2013 single-center RCT of 921 patients with acute UGIB found a restrictive transfusion strategy (transfusion threshold < 7 g/dL with target hemoglobin of 7–9 g/dL) significantly decreased 6-week mortality, length of stay, and transfusion-related adverse events compared with a liberal transfusion strategy (transfusion threshold < 9 g/dL with target hemoglobin of 9–11 g/dL).<sup>56</sup> The overall mortality benefit conferred by the restrictive transfusion strategy appears to have been driven by results obtained in patients with Child-Pugh class A and B cirrhosis. The subgroup of patients with NVUGIB did not exhibit a significant decrease in their overall mortality with a restrictive

transfusion policy, although there was a trend towards benefit with no suggestion of harm. Importantly, this study excluded all patients presenting with severe hemorrhagic shock, acute coronary syndrome, symptomatic peripheral vasculopathy, stroke, or transient ischemic attack in keeping with consensus guidelines, suggesting higher hemoglobin targets for some of these patients.

Current guidelines suggest that patients with hemoglobin levels of 7 g/dL or less should receive blood transfusions to reach a target hemoglobin level of 7–9 g/dL, provided that the individual has no coronary artery disease, evidence of tissue hypoperfusion or acute hemorrhage.<sup>5</sup> In patients with acute coronary syndrome, UGIB is associated with a markedly increased mortality, and a higher hemoglobin target level, above 10 g/dL, may be required.<sup>57,58</sup>

As part of a recent UK audit, despite 73% of patients with UGIB presenting with a hemoglobin level greater than 8 g/dL, approximately 43% received red blood cell transfusions.<sup>59</sup> A recently published metaanalysis (2014) not restricted to NVUGIB suggests that a restrictive transfusion approach reduces health care associated infections.<sup>60</sup> Additional randomized trials are needed to address the issue of hemoglobin transfusion thresholds in patients with NVUGIB, including patients with significant cardiac disease. One large multicenter randomized trial is currently being completed in the United Kingdom, which may help answer such uncertainties.<sup>61</sup>

## Platelet Transfusion

A 2012 systematic review of 18 studies examining platelet transfusion thresholds in patients with NVUGIB found insufficient evidence supporting an optimal platelet count.<sup>62</sup> However, based

primarily on expert opinion, the authors proposed a platelet transfusion threshold of  $50 \times 10^9/L$  (or  $100 \times 10^9/L$  if altered platelet function is suspected). Additional high-quality data are needed to confirm these recommendations.

## REVERSAL OF ANTICOAGULATION

Many patients who present with NVUGIB will be on anticoagulation for a variety of reasons, most commonly due to atrial fibrillation. Of these patients, many are on warfarin, which can be monitored using the international normalized ratio (INR). Several retrospective studies have shown no difference in rebleeding, mortality, length of stay, or transfusion requirements between patients with an INR between 1.3 and 2.7.<sup>67</sup> One cohort study compared patients with UGIB not on anticoagulation to patients on warfarin that had their INR corrected to 2.5 or under using fresh frozen plasma.<sup>68</sup> They found no differences in rebleeding, surgery, mortality, or complication rates between the two groups. As such, upper endoscopy (EGD) in patients with therapeutic INR levels on warfarin appears to be safe to allow for early endoscopy. Current guidelines suggest that endoscopy should not be delayed to correct anticoagulation in patients on warfarin who have a therapeutic INR.<sup>2</sup> For patients with an INR above 3, rapid reversal can be considered with either prothrombin complex concentrate or fresh frozen plasma in addition to vitamin K.<sup>69</sup>

Several new direct-acting oral anticoagulants are commonly prescribed to patients given their higher efficacy at preventing stroke and systemic thromboembolism in patients with atrial fibrillation.<sup>70</sup> These direct-acting anticoagulants now account for approximately 62% of all prescriptions for nonvalvular atrial fibrillation within the United States.<sup>71</sup> Some of these drugs may increase GI bleeding when compared to warfarin.<sup>68,69</sup> One major concern with these direct-acting oral anticoagulants is that there is no reliable way to monitor their efficacy on routine blood work.<sup>70</sup> Furthermore, only dabigatran (Pradaxa) currently has an approved reversal agent, known as idarucizumab (Praxbind), whereas reversal for the other agents await commercialization in most countries.<sup>71</sup> At this time, there are no clear guidelines as to the precise management of NVUGIB patients taking these newer anticoagulants.<sup>72</sup> There have been some reports of clotting factors such as fresh frozen plasma, activated factor VII, or prothrombin complex concentrate being used for partial reversal of anticoagulation.<sup>73</sup> Experts have suggested that early consultation with a hematologist and/or cardiologist should be considered in all patients with suspected GI bleeding on any of the direct acting oral anticoagulants.<sup>74</sup>

## TIMING OF ENDOSCOPY

The timing of endoscopic evaluation depends on patient factors (hemodynamic stability, airway protection) and hospital factors (monitored setting, availability of endoscopic expertise, dedicated nurses and equipment). Several studies have confirmed that emergency endoscopy (within 6–12 hours) for UGIB has no advantage in terms of rebleeding, surgical rates, or mortality when compared to routine endoscopy within 24 hours.<sup>75,76</sup> In one large retrospective study of 934 patients, Lim et al (2011) found that early endoscopy (defined as endoscopy within 13 hours of presentation) was associated with a lower mortality rate for high-risk patients with GBS scores of 12 or higher.<sup>77</sup> Interestingly, there was no difference in rebleeding rate, transfusion

requirements, or surgery. Moreover, for low-risk patients with GBS scores less than 12 there were no differences in any outcomes when comparing early endoscopy to endoscopy within 24 hours of presentation. There is ongoing controversy as to the existence of a "weekend effect" whereby mortality from UGIB may be higher after regular working hours compared with patients treated at other times. Some authors postulate this effect may be due to a patient selection bias (sickest presenting at any time, including after hours) or decreased resources including delays to endoscopy and other treatments.<sup>78–81</sup>

Current guidelines suggest that endoscopy should be performed within 24 hours in all patients presenting with UGIB who are admitted to hospital because this practice has been shown to decrease length of stay, rebleeding rates, and need for surgery.<sup>2</sup> Some experts believe that, based on the limited evidence, endoscopy should be considered within 12 hours in selected high-risk patients.<sup>12,82</sup>

## Prokinetics

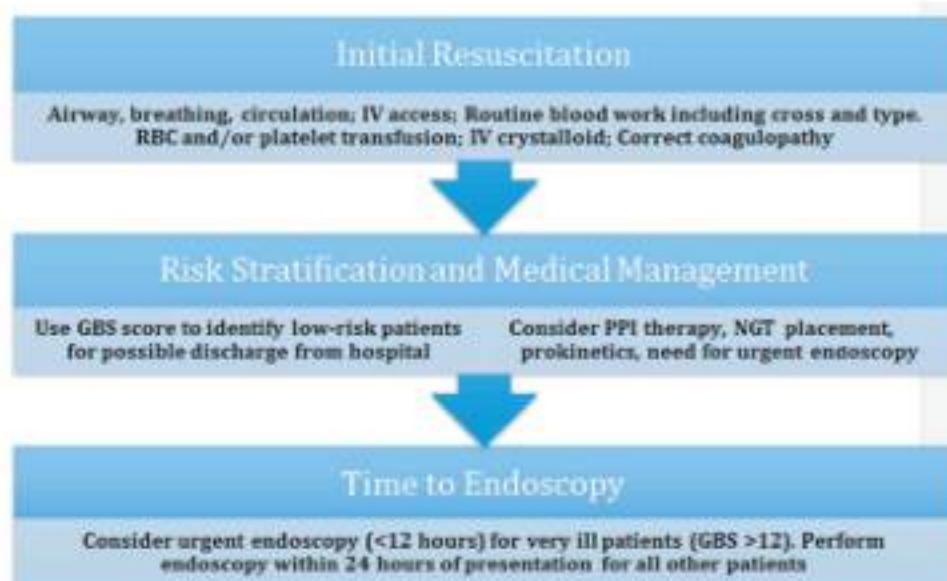

The use of prokinetic agents (such as erythromycin) before GI endoscopy has been shown to significantly shorten the duration of endoscopy, reduce the need for repeat endoscopy, and decrease the need for blood transfusions.<sup>83–87</sup> In a large, multicenter RCT involving 253 patients presenting with either melena or hematemesis, erythromycin alone was equally efficacious at improving endoscopic visualization as NGT aspirate alone or in combination with erythromycin.<sup>88</sup> One metaanalysis which included 313 patients found that either intravenous erythromycin or metoclopramide immediately before EGD in patients with UGIB decreased the need for repeat endoscopy, but did not improve other clinically relevant measurable outcomes.<sup>89</sup>

More recently, another small-sized, low-quality randomized trial (2013) compared NGT aspirate alone versus NGT aspirate with erythromycin and found the combination provided superior visualization, reduced hospital admissions, and decreased blood transfusions.<sup>90</sup> No data suggest that the administration of prokinetic agents can decrease mortality, the risk of rebleeding, or the need for surgery.<sup>84–86,88</sup> Nonetheless, given improved visibility at endoscopy and other potential benefits discussed previously, especially in light of the favorable benefit-harm profile of erythromycin, current guidelines suggest that after ruling out contraindications to these agents (such as hypokalemia or a prolonged QT interval) a 250 mg bolus of erythromycin should be administered approximately 30 to 45 minutes prior to endoscopy. This recommendation is for patients with clinical evidence of active hemorrhage (hematemesis or melena) or acute anemia requiring resuscitation, or in those who have recently eaten, but should not be used routinely in all patients presenting with UGIB.<sup>12,82</sup>

## Preendoscopic Proton Pump Inhibitors

Despite theoretical pharmacological differences between the different proton pump inhibitors (PPIs), no data support the use of a particular intravenous PPI over another when treating patients with UGIB. In the rest of this chapter, PPI will be used as a generic term for all such agents.

Starting PPI treatment before endoscopy for UGIB remains a controversial practice. A metaanalysis that included 2,223 participants from six randomized, clinical trials found that preendoscopic PPI treatment reduces the proportion of patients identified as having high-risk lesions (active bleeding, non-bleeding visible vessel, and adherent clot) thus reducing the need

**FIG 14.1** Steps for Initial Management of Upper Gastrointestinal Bleeding. GBS, Glasgow-Blatchford score; IV, intravenous; NGT, nasogastric tube; PPI, proton pump inhibitor; RBC, red blood cell.

for endoscopic therapy (i.e., down-staging of high-risk endoscopic lesions).<sup>30</sup> Despite these advantages, there is no evidence that preendoscopic PPI treatment affects mortality, risk of rebleeding, or need for surgery. For this reason, current guidelines recommend initiating PPI therapy on presentation to hospital, although it should never delay optimal resuscitation.<sup>2</sup> PPI therapy pre-endoscopy is especially cost-effective in certain scenarios: when endoscopy is delayed for more than 16 hours after admission, or if patients have a high likelihood of nonvariceal bleeding, especially in those with high-risk symptoms, such as hematemesis.<sup>30,31</sup> Current guidelines advise against the use of histamine-2 receptor antagonists in acute ulcer bleeding.<sup>2</sup>

No recommendations can be made regarding the optimal dose or optimal route of administration of PPIs administered preendoscopy. A reasonable strategy may be to adopt a high-dose intravenous bolus (e.g., 80 mg) followed by a continuous infusion (e.g., 8 mg/hour) regimen.<sup>32</sup> This infusion can be continued until endoscopy, at which point reassessment is required depending on the appearance of the bleeding lesion and the need for therapeutic intervention (see section on postendoscopic PPI therapy). A recent budget impact analysis assessing PPI institutional costs both pre- and postendoscopy suggest minimal incremental costs when opting for high-dose PPI infusion<sup>33</sup> (Fig. 14.1).

## Etiology of Nonvariceal Upper Gastrointestinal Bleeding

The most common causes of NVUGIB include: gastroduodenal ulcers, angiomyolipoma, Dieulafoy lesions, Mallory-Weiss tears (MWT), malignancy, esophagitis, and erosive gastritis among other causes.<sup>34-36</sup> Endoscopy allows for both the diagnosis and treatment of these lesions. The relative frequency of the causes of UGIB from a recent audit of 5004 patients presenting with UGIB can be seen in Table 14.2.<sup>37</sup>

**TABLE 14.2 Frequency of Endoscopic Diagnoses for Patients Presenting With Upper Gastrointestinal Bleeding**

Endoscopic Diagnosis	Frequency
Peptic ulcer disease	36%
Esophagitis	24%
Gastritis or gastric erosions	22%
Erosive duodenitis	13%
Esophageal or gastric varices	11%
Portal hypertensive gastropathy	5.5%
Mallory-Weiss tear	4.3%
Upper GI malignancy	3.7%
Angiodysplasia or vascular lesion	2.7%
Summary of Findings	Frequency
One diagnosis found	50%
Two or more diagnoses found	31%
No abnormality seen	19%

Modified from Hehir/Saw SA, Logan RF, Lowe D, et al: Use of endoscopy for management of acute upper gastrointestinal bleeding in the UK: results of a nationwide audit. Gut 59(8):1022-1029, 2010.

## Indications for Endoscopic Therapy for Gastroduodenal Ulcers

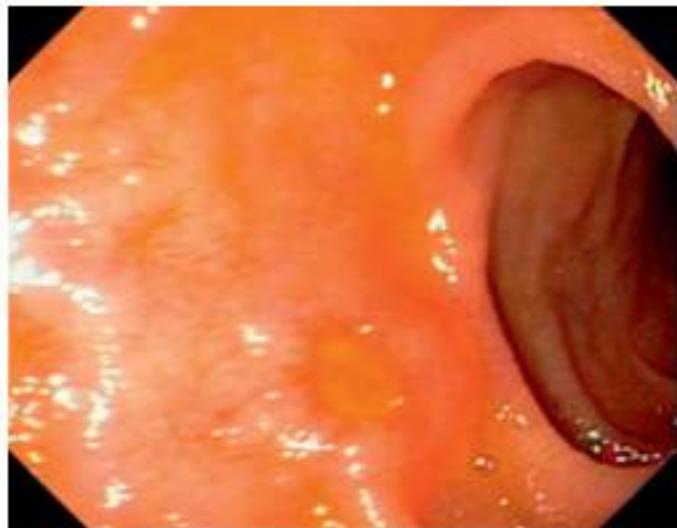

The role of endoscopic therapy for the management of gastroduodenal ulcers is based on the Forrest classification, which categorizes ulcer into high and low risk in terms of rebleeding risk (Table 14.3).<sup>38-40</sup> Several studies have since validated the Forrest classification in terms of predicting risk of rebleeding and the need for endoscopic intervention.<sup>41,42</sup> Overall, endoscopic

**TABLE 14.3 Risk of Rebleeding Peptic Ulcer Disease Despite Medical Management Alone Based on Forrest Classification on Initial Endoscopic Evaluation**

Endoscopic Stigmata (Forrest)	Frequency	Rebleeding on Medical Management
Spurting vessel (Ia)	10%	90%
Oozing vessel (Ib)	10%	10–20%
Nonbleeding visible vessel (Ia)	25%	50%
Adherent clot (IIb)	10%	25–30%
Flat pigmented ulcer base (IIC)	10%	7–10%
Clean-based ulcer (III)	35%	3–5%

**TABLE 14.4 Forrest Classification for Endoscopic Appearance of Gastroduodenal Ulcers**

Forrest Classification	Endoscopic Appearance	Endoscopic Therapy
Ia	Spurting vessel	Therapy required
Ib	Oozing vessel	Therapy required
IIa	Nonbleeding visible vessel	Therapy required
IIb	Adherent clot	Consider therapy
IIc	Flat pigmented ulcer base	No therapy required
III	Clean-based ulcer	No therapy required

**FIG 14.2** Duodenal ulcer classified as Forrest class III (i.e., clean-based).

therapy is required for patients with ulcers classified as Ia, Ib, or IIa, and is controversial for patients with an adherent clot (see section titled Nonbleeding Adherent Clot).<sup>102–106</sup> For ulcers with IIc and III classification (Fig. 14.2), endoscopic therapy is not warranted, as rebleeding risks are low (Table 14.4; Fig. 14.3).<sup>28</sup>

### Nonbleeding Adherent Clot

The endoscopic management of an adherent clot overlying an ulcer base remains controversial in the literature (Fig. 14.4). Consideration must be given to endoscopic removal of the clot and treatment of the underlying lesion if it satisfies criteria for high-risk stigmata (e.g., Forrest classification IA, IB, or IIa). Vigorous irrigation of the clot using a water pump has been shown to expose the underlying stigmata in 26%–43% of cases, of which 70% were high risk stigmata requiring endoscopic therapy.<sup>105,106</sup> The rebleeding risk for clots that remain despite irrigation has been estimated between 0%–35% in several studies.<sup>104,105,107,108</sup> One metaanalysis of 6 RCTs comprising 240 patients with adherent clots found that although endoscopic therapy was associated with a lower rebleeding risk than medical therapy alone (8.2% vs. 24.7%,  $p = 0.01$ ), other endpoints, including length of hospital stay (6.8 vs. 5.6 days;  $p = 0.27$ ), transfusion requirements (3.0 vs. 2.8 units;  $p = 0.75$ ), and mortality (9.8% vs. 7%,  $p = 0.54$ ), were no different between the two groups.<sup>103</sup> This metaanalysis did have several limitations including the vastly different patient populations, and statistical tests used to assess the impact of heterogeneity.<sup>109</sup>

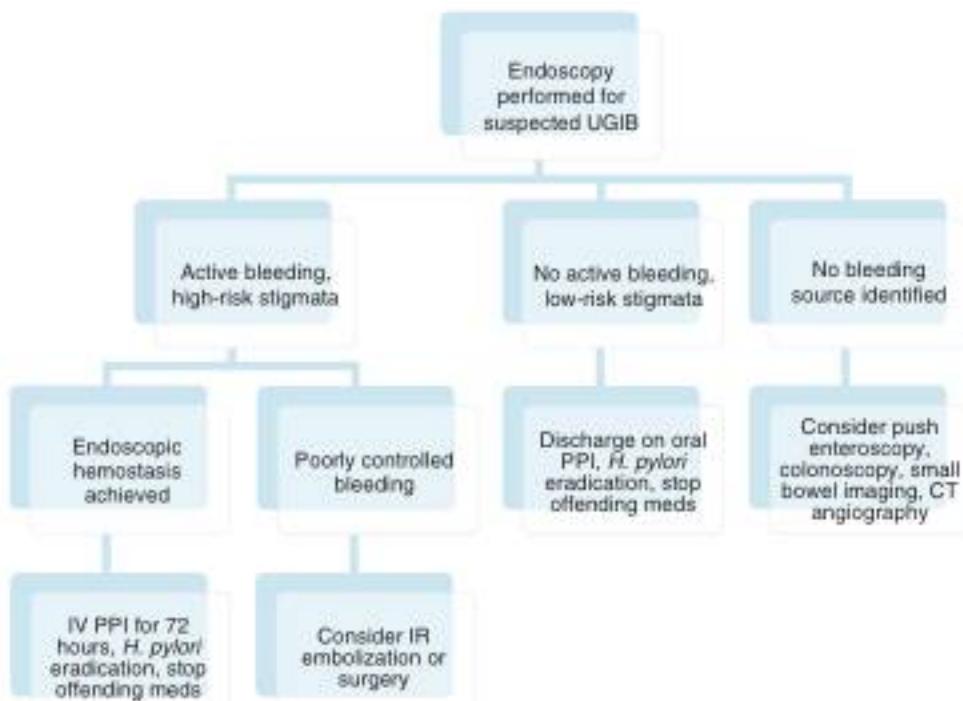

Endoscopic therapy for adherent clots consists of preinjection with epinephrine followed by removing the adherent clot using a cold snare. Once the clot is removed, combination therapy can be applied to the underlying stigmata as indicated.<sup>104,108</sup> One 2015 observational study suggested that endoscopic therapy was preferred over conservative therapy alone for adherent clots in terms of mortality but did not demonstrate lower rebleeding rates.<sup>102</sup> Future multicenter randomized controlled studies are required to better identify patients who may benefit from endoscopic intervention compared to PPI therapy alone.

### MODALITIES FOR ENDOSCOPIC THERAPY

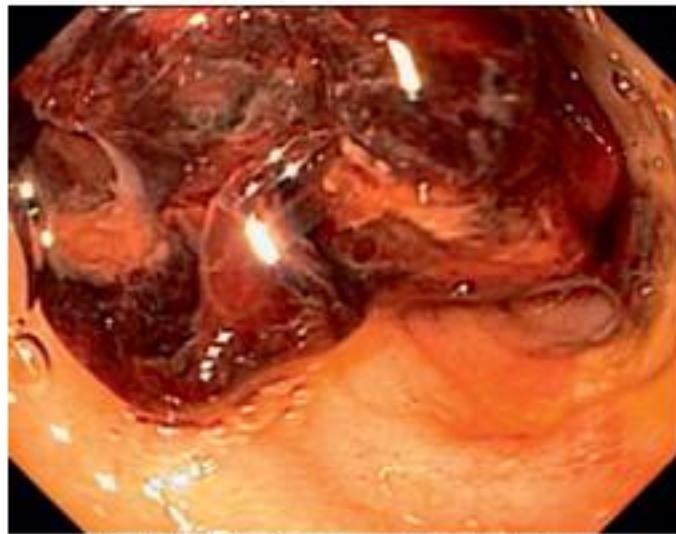

The most commonly used endoscopic techniques for management of a bleeding ulcer include: injection therapy, thermal coaptive therapy, endoscopic clipping, and hemostatic powders.<sup>110</sup> Each method has its strengths and weaknesses and often more than one technique can be used for a given case.<sup>111</sup> Each modality will be discussed separately, including the role of combination therapy.

#### Injection Therapy

Epinephrine is the most established injection agent used for peptic ulcer injection therapy, although studies have been done using normal saline along with a sclerosant agent.<sup>112</sup> The mechanism of action is thought to be local tamponade and vasoconstriction (Fig. 14.5). Epinephrine diluted to 1:10,000 in normal saline is found to be most effective and safest. A large RCT of 165 patients with actively bleeding ulcers or visible vessels was performed to determine the ideal amount of epinephrine injection (1:10,000). This RCT, which was largely representative of the existing literature, found that large volume injection (13–20 mL) compared to small volume injection (5–10 mL) was associated with less rebleeding (15.4% vs. 30.8%,  $p = 0.037$ ).<sup>113</sup> A large metaanalysis of 1673 patients revealed that epinephrine injection alone is inferior to either clips or thermal therapy.<sup>114</sup> An additional metaanalysis confirmed these findings.<sup>115</sup> One of the roles of epinephrine injection is to temporize and control bleeding to achieve better visualization and so apply more definitive therapy (e.g., thermal therapy or clipping) to the lesion. Overall, injection

**FIG 14.3** Approach to Endoscopic Management of Upper Gastrointestinal Bleeding (UGIB). CT, computed tomography; IR, interventional radiology; IV, intravenous; PPI, proton pump inhibitor.

**FIG 14.4** Duodenal ulcer with adherent clot.

therapy is a useful technique to incorporate into the management of ulcer bleeding but should not be used as monotherapy.

#### Technique for Injection

A disposable injection needle with a retractable tip is used. The most commonly used needles are the 23- or 25-gauge needles, with a needle length of approximately 3 to 5 mm.<sup>116</sup> Injection is undertaken in 0.5- to 2.0-mL increments in all four quadrants around the target lesion because the path of the underlying artery is often unknown.<sup>117</sup> Randomized studies found that a total volume of 20 to 45 mL may be injected to achieve the desired results, although the studies were performed using

monotherapy.<sup>113,118</sup> In the setting of active bleeding, if the initial injection results in noticeable slowing and, more so, cessation of bleeding, a single injection site may suffice. Additional volume may be injected via a single site as long as any lifting effect does not impair access to the bleeding vessel for second-line therapy with coaptive coagulation or hemoclips.

#### Thermal Coaptive Therapy

The most widely used modalities to provide contact thermal therapy include the bipolar probes (delivers electrical current) and the heater probe (aluminum garnet that provides heat). The advantages of these devices are their excellent efficacy, safety, portability, cost, and for some, the ability to combine irrigation, and coagulation.<sup>119–122</sup> The probes are used to place manual compression over the lesion to tamponade the bleeding vessel and obliterate the lumen of the offending arteriole in the base of the bleeding lesion through so-called coaptive electrocoagulation (Fig. 14.6). Regardless of the probe being used, the endpoint for successful hemostasis for contact thermal hemostasis, especially when treating large arteries, is firm pressure on the bleeding lesion until a "footprint" is obtained.<sup>118</sup>

Coagulation can be achieved by using either the tip or side of the probe depending on the location, but *en-face* treatment is favored. Specific details about the two most commonly used probes are given in the following sections. Other forms of thermal therapy have recently been assessed, such as using soft coagulation delivered with hemostatic forceps, as is done for endoscopic mucosal resection and endoscopic submucosal dissection. Comparative trials amongst treatment modalities are few, but a recent RCT compared the effectiveness of soft coagulation using hemostatic forceps with a heater probe in 111 patients presenting with ulcer bleeding. Overall, patients randomized to hemostatic forceps had lower rebleeding rates, fewer perforations, and fewer surgeries.<sup>123</sup>

**FIG 14.5** **A**, Duodenal ulcer with visible vessel injected with epinephrine causing vasoconstriction evidenced by **B**, blanching of the mucosa.

**FIG 14.6** Firm application of heater probe onto visible vessel of duodenal ulcer to obtain a "footprint."

In one metaanalysis, the use of thermal coaptive therapy for patients with high-risk lesions was shown to reduce rebleeding (OR 0.44), need for surgery (OR 0.39), and mortality rates (OR 0.58) when compared with no endoscopic treatment.<sup>113</sup> In a separate metaanalysis the impact on mortality was not reproduced (OR 0.64).<sup>114</sup> Although pooled metaanalytical data comparing thermal monotherapy with the combination of injection and thermal therapy did not reveal any significant differences in rebleeding, subgroup analysis favored combination therapy after two less generalizable trials were removed, resulting in decreased risks of rebleeding (OR 0.37).<sup>114</sup>

#### Bipolar Probe Technique

The technique for applying bipolar electrocoagulating energy has not been standardized and varies among reported clinical trials. One expert recommends forcefully applying a large

(3.2-mm) bipolar circumactive probe (BICAP) on a power setting of 3 to 5 for a prolonged duration, such as 14 seconds, or seven pulses of 2 seconds each.<sup>125</sup> Another expert used a setting of 3 or 4 with 10-second pulses on a BICAP II generator.<sup>126</sup>

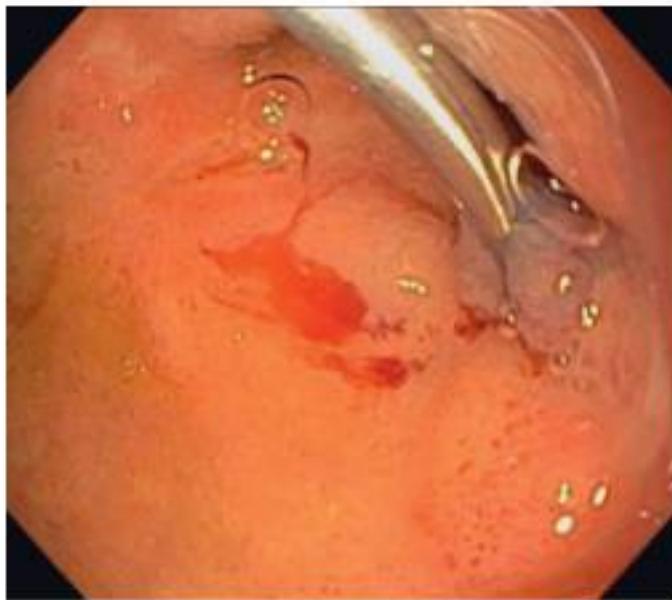

#### Heater Probe Technique

The present technique for bleeding peptic ulcers involves using the larger heater probe and placing firm tamponade directly on the bleeding point or visible vessel, and coagulation with at least 120 J (four pulses of 30 J each) before moving the probe.<sup>127,128</sup> An additional application of energy when using the heater probe or bipolar probes as the probe is removed from the treatment site can reduce unwanted tissue adhesion and the inadvertent tearing of the coagulated sealant with resultant rebleeding.<sup>129,130</sup>

#### Argon Plasma Coagulator

Argon plasma coagulation (APC) is a noncontact method that allows for controlled electrocoagulation via high-frequency monopolar energy to be delivered to the tissue through an ionized gas (argon plasma). In a large retrospective study of 194 patients presenting with a visible vessel overlying an ulcer, APC was equally effective as hemoclips in controlling bleeding in terms of rebleeding rate, need for transfusion, and mortality.<sup>131</sup> In a prospective trial of 41 patients, Cipolletta et al (1998) compared APC with heater probe therapy; rates of initial hemostasis, recurrent bleeding, emergency surgery, and 30-day mortality were comparable in both groups.<sup>132</sup> Chau et al (2003) reported similar results in a large (185 cases) randomized trial comparing epinephrine plus heater probe with epinephrine plus APC.<sup>133</sup>

APC has proven to be an effective therapy for managing angiomyxomatous lesions as evidenced by a reduction in need for transfusion and surgery.<sup>134</sup> Importantly, however, recurrence of these lesions, in spite of any therapy, is evident in approximately one-third of patients. One 2016 cohort study of 53 patients found that APC treatment as opposed to no endoscopic treatment did not improve 30-day rebleeding rates or mortality rates in patients presenting with UGIB secondary to a malignancy.<sup>135</sup> Overall, APC appears to be an effective, safe, and relatively low cost alternative that can be used for many different causes of UGIB including peptic ulcers, angiomyxomatous lesions (including

**FIG 14.7** Duodenal ulcer treated with endoscopic clip.

gastric antral vascular ectasia), and perhaps malignancy related bleeding.<sup>136–138</sup>

### Endoscopic Clipping

The underlying mechanism of clips is the mechanical ligation of the bleeding vessel (Fig. 14.7). Most studies have been performed on first-generation clips. Clips are easier to apply with the scope in the straight position. An example of an endoscopic clip being applied to an actively bleeding peptic ulcer can be seen in Video 14.1. Tangential access makes application a challenge because of the simple mechanics allowing the clip to be extruded from the catheter, opened, and finally closed.<sup>139</sup> Other regions shown to be difficult to clip include the posterior wall of the antrum and the superior duodenal recess.<sup>140</sup> The advantages of using clips include that no additional equipment is required, there is no thermal injury or special setup, and they are easily applied. The one drawback is the cost associated with disposable clips and that some clips may not deploy properly and must then be discarded. The proposed method of deploying the clip is to visualize the ulcer or visible vessel and to capture the lesion within the clip. When applying the clip, it should be maximally opened and gentle pressure applied with the clip over the lesion. Using suction to help approximate the edges helps capture tissue and then the clip is deployed. Sometimes additional clips are required to adequately achieve hemostasis.

One metaanalysis of 4261 patients found that any form of endoscopic treatment was superior to pharmacotherapy alone.<sup>128</sup> Optimal endoscopic therapies include thermal therapy or clips, either alone or in combination with other methods. Interestingly, injection followed by thermal therapy did not decrease rebleeding compared with clips (OR 0.82) or thermal therapy alone (OR 0.79). Overall, clips were superior to thermal therapy (OR 0.24) but, when followed by injection, were not superior to clips alone (OR 1.30).

Several RCTs investigating the use of endoscopic clips alone or in combination with other endoscopic modalities have reported variable success. The most important factor seems to be the location of the lesion, such as high on the lesser curvature and posterior duodenal wall, which are challenging locations for clip

deployment.<sup>141</sup> Improvements in endoscopic clip devices have included single-use, rotatable, and reopening features.<sup>142</sup> Lastly, in certain cases endoscopic therapy may be unsuccessful at controlling acute bleeding; for these situations, placing clips near the site of the bleeding can help interventional radiologists localize the site for embolization.<sup>143</sup>

### Combination Therapy

There is a theoretical advantage of combining therapies because hemostasis is achieved by different mechanisms. Combination therapy with injection and coaptive therapy has consistently shown superiority over medical therapy.<sup>144</sup> In a prospective study by Bianco et al (2004), combined therapy with epinephrine injection with bipolar probe showed better results than epinephrine alone.<sup>145</sup> Most of the RCTs looking at combination therapy with clips and injection therapy utilize clips prior to injection to avoid possible displacement of the clip as the tissue edema resorbs.

Calvet et al (2004) performed a metaanalysis of trials comparing epinephrine injection alone with epinephrine plus a second method (thermal, mechanical, sclerosant) for patients with UGIB.<sup>144</sup> The analysis included 16 studies of 1673 patients who had high-risk stigmata of bleeding defined by Forrest criteria IA, IIA, and IIB. Addition of a second endoscopic method reduced rate of rebleeding (18.4% vs. 10.6%), need for surgery (11.3% vs. 7.6%), and mortality (5.1% vs. 2.6%) compared with epinephrine injection alone. Risk of further bleeding decreased regardless of the type of second method used. Risk of significant complications, including massive bleeding, gastric wall necrosis, and perforation, was the same in both groups (1.1%).

A recent Cochrane review metaanalysis from 2014 compared combination therapy versus monotherapy with epinephrine injection alone in patients with high-risk peptic ulcer bleeding. This review included 2033 patients and found that combination therapy (i.e., epinephrine injection with either injection of another substance, coaptive therapy, or mechanical clipping) was more effective than monotherapy with epinephrine injection alone. Specifically, combination therapy had a significantly lower risk of rebleeding (relative risk [RR] 0.53), the need for surgery (RR 0.68), and mortality (RR 0.50). Overall, combination therapy was associated with a reduced risk of rebleeding (RR 0.57), a reduced need for emergency surgery (RR 0.68) and a lower mortality (RR 0.50).<sup>146</sup> Sub-analysis was unable to determine which combination therapy was most effective.

### Hemostatic Powders

Various hemostatic powders are a new and emerging modality being used for the management of patients with UGIB. The advantage of these powders is their noncontact and nontraumatic application whereby a bleeding lesion is sprayed with the powder. This treatment modality also allows for treatment of large surface areas and does not require the same precision as other interventions like coaptive therapy or clipping. Some powders require direct application to an actively bleeding lesion.<sup>147,148</sup> Available products for endoscopic application include Tc-325 (Hemospray, Cook Medical, Bloomington, IN), Endoclot TM (EndoClot Plus, Inc., Santa Clara, CA), and Ankaferd (Ankaferd Health Products Ltd., Turkey). Data and availability of some of these products are limited and thus we will concentrate on the discussion on Tc-325 (Hemospray). For a more complete description of other available powders, readers can refer to a 2015 review article.<sup>149</sup>

Systematic reviews of case series suggest Tc-325 is extremely effective in achieving immediate hemostasis.<sup>149</sup> Additional roles

may exist for Tc-325 as rescue therapy, arresting bleeding for transfer to a site with more expertise in endoscopic hemostasis and malignant bleeding. There has only been one reported RCT to date (in patients exhibiting high-risk ulcer lesions) suggesting worsened efficacy if used in peptic ulcer disease bleeding owing to the limited 12–24-hour residency time of the powder that is exceeded by the 72-hour delayed rebleeding period following endoscopic hemostasis.<sup>147–149</sup>

The largest multicenter study to date included 63 patients with NVUGIB of which 55 (87%) patients had Tc-325 used as initial monotherapy to control bleeding.<sup>150</sup> Hemospray was effective as monotherapy at controlling bleeding in 85% (47/55) of patients and the rebleeding rate was 15% at 1-week. Of the 8 patients who were managed with traditional endoscopic therapy at initial presentation, Tc-325 effectively managed all episodes of rebleeding and prevented the need for interventional radiology or surgery. Several additional studies, including one metaanalysis, have shown similar results in terms of initial management and recurrent bleeding with the use of Tc-325, including use in patients with thrombocytopenia and those on anticoagulation.<sup>151–154</sup>

Other indications that seem to have derived benefit from the use of hemostatic powders include anastomotic ulcer bleeding, ischemic colitis, and postpolypectomy bleeding.<sup>155–157</sup> Importantly, Tc-325 is a temporary treatment and is not recommended as monotherapy for lesions with a high risk of rebleeding such as peptic ulcers with high-risk stigmata.<sup>152</sup> Tc-325 may still be used in these situations, but only in combination with more definitive ulcer therapy as discussed previously.<sup>151</sup> Future studies will delineate the precise use of Tc-325 in various patients and compare its use to traditional endoscopic therapies. Given its ease of use and apparent safety, Tc-325 appears to be at the very least a cost-effective option for temporizing bleeding while more definitive therapeutic options are being considered.<sup>158</sup>

## POSTENDOSCOPIC PROTON PUMP INHIBITORS

The goal of PPI therapy is to raise the gastric pH sufficiently to promote clot stability and to reduce the effect of pepsin and gastric acid.<sup>159</sup> In a study that aimed to identify the lowest effective dose of PPI, rather than using a high (or low) dose, continuous infusion was the key to maintain an intragastric pH above 6.<sup>160</sup> Two metaanalyses have confirmed that an intravenous PPI bolus followed by continuous PPI infusion over 72 hours reduces the rates of mortality (RR = 0.40, 0.28–0.59; number needed to treat [NNT] = 12), rebleeding (RR = 0.40, 0.28–0.59; NNT = 12), and surgery (RR = 0.43, 0.24–0.76; NNT = 28). Mortality was only reduced in patients who had previously undergone successful endoscopic hemostasis.<sup>115,161</sup> Cost-effectiveness analyses have demonstrated the economic dominance of high-dose intravenous PPI over no treatment strategies, principally due to the high incremental cost of an additional hospitalization for rebleeding in light of the modest NNT.<sup>162</sup>

More recently, a systematic review and metaanalysis (2014) compared intermittent versus continuous PPI therapy for the treatment of high-risk bleeding ulcers after endoscopic therapy.<sup>163</sup> This study revealed that intermittent PPI therapy may be as effective as continuous infusion high-dose therapy in these high-risk patients, which may have benefits in terms of cost-savings, and the authors firmly conclude that guidelines should be revised to recommend intermittent PPI therapy. Current guidelines remain ambivalent towards optimal postendoscopy PPI dosing due to an overall lower quality of evidence secondary

to a high risk of bias and imprecision in the aforementioned systematic review.<sup>12</sup>

High-dose oral PPI treatment after endoscopy was efficacious in early trials conducted in India and Iran, but differences in the physiological and pharmacokinetic characteristics of the patients, as well as local high *Helicobacter pylori* carriage rate and limited comorbidities make the results of these studies difficult to apply to other populations. The endoscopic treatment administered was also not the current recommended standard.<sup>164</sup> A further study published in 2009 assessed gastric pH in patients receiving a 90-mg oral dose of lansoprazole followed by 30 mg every 3 hours (total dose 300 mg in 24 hours) after successful endoscopic treatment for peptic ulcer bleeding.<sup>165</sup> The primary endpoint was the proportion of the 24-hour period that the patients had a gastric pH greater than 6 (median 55%). However, large differences in this value were evident between individuals (range 6%–99%), and only 1 of 14 patients (7%) reached a pH above 6 in at least 80% of this time.<sup>165</sup> Accordingly, the evidence is insufficient to support the use of oral PPI therapy immediately after endoscopy in high-risk patients. Current recommendations are for oral PPI therapy in patients with lower-risk stigmata on endoscopy, such as a clean-based ulcer or a flat-pigmented spot.<sup>166</sup>

A recent RCT of 293 patients investigated the efficacy of double-dose oral PPI (esomeprazole 40 mg PO twice daily for 11 days, followed by once daily dosing for another 14 days) compared to single-dose oral PPI (esomeprazole 40 mg PO once daily for 25 days) after 3 days of intravenous PPI infusion for patients with high Rockall scores of 6 or higher at increased risk for rebleeding.<sup>167</sup> Cheng et al (2014) found less rebleeding rates with the twice-daily PPI regimen (10.8% vs. 28.7%,  $p = 0.002$ ). We recommend routinely prescribing double-dose PPI for at least 14 days following intravenous PPI infusion in these high-risk patients and single dose thereafter.

The decision to continue oral PPI past 28 days must be judged on an individualized basis as there is insufficient evidence to guide practice and it is determined by the nature of the bleeding lesion. For example, longer courses of PPI therapy may be warranted for patients with bleeding erosive esophagitis compared to a patient with a duodenal ulcer.<sup>2</sup> The optimal duration of treatment with oral PPI is unknown and also depends on patient ongoing risk factors, and sometimes the severity of the presentation. For example, a patient treated for peptic ulcer disease related to either *H. pylori* or nonsteroidal antiinflammatory drug (NSAID) use, may only require a short course of PPI so long as the *H. pylori* is eradicated or the NSAID discontinued.<sup>2,12</sup> The benefits and risks of ongoing PPI therapy should be discussed with individual patients.<sup>168</sup>

## SECOND-LOOK ENDOSCOPY

Prior to the widespread use of PPI therapy for peptic ulcer disease, several studies suggested that routine second-look endoscopy could be utilized for the purpose of preventing rebleeding.<sup>169–172</sup> More recently, Chiu et al (2016) randomized 305 patients with a high-risk peptic ulcer (either actively bleeding or a visible vessel) to either an intravenous PPI infusion or intravenous PPI bolus along with a second-look endoscopy within 24 hours after the initial endoscopy.<sup>173</sup> Based on the results of this RCT, there was no significant difference in rebleeding, transfusion requirements, need for surgery, or mortality between the two groups. A metaanalysis by El Ouali et al (2012) that included this trial

in abstract form, suggested that the only compelling evidence for second look endoscopy is in patients with peptic ulcers exhibiting high-risk stigmata who did not undergo modern recommended endoscopic therapy or who were not provided PPI therapy.<sup>162</sup> Current guidelines do not recommend routine second-look endoscopy but rather only to be considered in patients who are at high risk for rebleeding.<sup>2,11</sup>

## PREVENTION OF RECURRENT BLEEDING

To prevent recurrent bleeding, underlying risk factors for recurrent bleeding must be identified and addressed. Patients undergoing endoscopic therapy for high-risk stigmata should be kept *nil per os* (NPO) for 24 hours, and hospitalized for 72 hours to provide intravenous PPI therapy.<sup>2</sup> Risk factors for peptic ulcer disease recurrence include presence of *H. pylori*, NSAID use, and the need for prolonged antiplatelet medications and/or anticoagulants.<sup>163,174</sup> Each risk factor will be addressed separately (Fig. 14.8). If there is no identifiable cause of the peptic ulcer (e.g., *H. pylori* negative, no aspirin or NSAID use), guidelines suggest indefinite long-term PPI therapy because the incidence of recurrent ulcer bleeding in this population has been reported at 42%.<sup>12,175,176</sup>

### NSAID Therapy

Any patient who develops peptic ulcer disease while on NSAID should be considered for either NSAID discontinuation or PPI prophylaxis.<sup>177</sup> If the NSAID can be discontinued, PPI therapy is only required for 4 to 8 weeks to allow for ulcer healing.<sup>178</sup> Often, however, NSAIDs must be continued either for either their pain management or antiinflammatory properties. Should NSAID treatment be necessary, guidelines recommend considering a COX-2-selective NSAID at the lowest possible dose along with daily PPI therapy.<sup>2,12,179</sup> Studies have shown a synergistic effect of *H. pylori* and NSAIDs with regard to UGIB so all patients who require ongoing NSAID therapy should be tested for *H. pylori* and treated as necessary.

### Antiplatelet Therapy

The indication for antiplatelet therapy must be considered and weighed against the risk of ongoing or recurrent bleeding. For

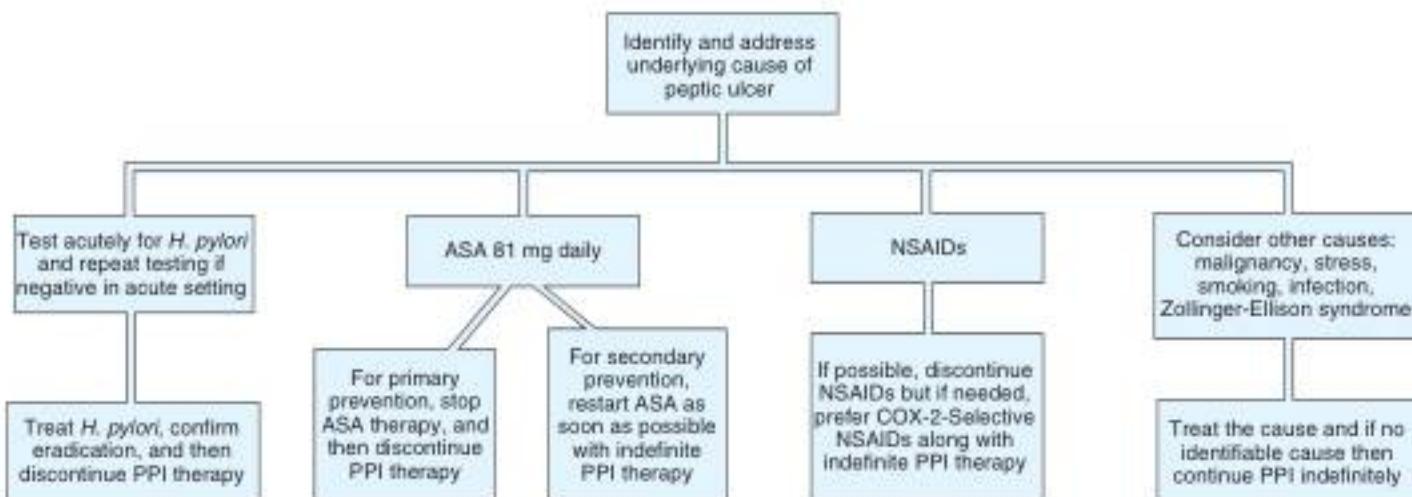

patients on aspirin for primary prevention, withholding the aspirin during acute bleeding and restarting it within 3–5 days is recommended by current guidelines based on RCT data suggesting increased overall mortality in the group in whom acetylsalicylic acid (ASA) was withheld for up to 2 months.<sup>11,180,181</sup> Certainly if there is no indication for aspirin therapy, then consultation with a cardiologist or neurologist may allow for discontinuation.

If aspirin is required for secondary prevention, long-term PPI therapy should be continued indefinitely to prevent rebleeding.<sup>12,181,182</sup> Pooled results of two RCTs<sup>183,184</sup> showed a significant reduction in rebleeding with ASA combined with PPI compared with clopidogrel alone (OR 0.06). There was no difference in cardiovascular events, cerebrovascular events, or mortality between the two groups.<sup>2</sup> *H. pylori* testing and eradication should be performed in all patients with peptic ulcer disease to reduce the risk of recurrent bleeding.<sup>2</sup>

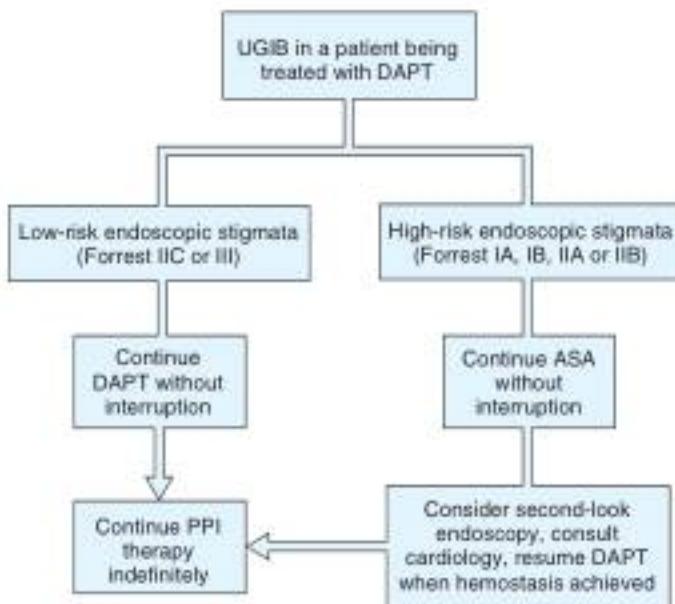

Current guidelines suggest primary, let alone secondary PPI prophylaxis in all patients who are on dual antiplatelet therapy after coronary artery stenting because the risk of bleeding on dual antiplatelet therapy is significantly higher than being on aspirin alone.<sup>185–187</sup> Although there was controversy regarding the effect of PPI on the efficacy of clopidogrel, one 2016 RCT of 1970 patients showed no detrimental effect of PPI when added to dual antiplatelet therapy.<sup>188</sup> There are no high-quality studies that address the important question of withholding or resuming dual antiplatelet therapy during a UGIB; however, due to the high risk of stent thrombosis, most guidelines suggest continuing aspirin and withholding clopidogrel in severe bleeding and considering resuming as soon as bleeding is adequately controlled.<sup>189</sup> Certainly, the endoscopist must weigh the risk of stent thrombosis with the perceived risk of rebleeding and often consultation with cardiology is helpful (Fig. 14.9).

### Restarting Anticoagulation

Many patients who present with UGIB are on anticoagulants on admission to hospital, and depending on the severity of bleeding, may have their anticoagulation interrupted during their hospitalization.<sup>190</sup> The ideal time to restart anticoagulation once the bleeding source has been controlled is unknown.<sup>2</sup> The

**FIG 14.8** Diagnosis and Management of Peptic Ulcers After Endoscopy. ASA, acetylsalicylic acid; NSAIDs, nonsteroidal antiinflammatory drugs; PPI, proton pump inhibitor.

**FIG 14.9** Approach to Management of Dual Anti-Platelet Therapy (Dapt) in Patients Presenting With Upper Gastrointestinal Bleeding (UGIB). ASA, acetylsalicylic acid; PPI, proton pump inhibitor. (Modified from Gralnek IM, Dumonceau JM, Kuipers EJ, et al: Diagnosis and management of nonvariceal upper gastrointestinal hemorrhage: European Society of Gastrointestinal Endoscopy (ESGE) Guideline. *Endoscopy* 47[10]:a1-a46, 2015.)

decision about restarting anticoagulation often depends on the perceived risk of rebleeding, as well as the indication for anticoagulation and the risks of its interruption. One retrospective study examined 1329 patients who were on warfarin at the time of major GI bleeding to see whether restarting anticoagulation afterwards was associated with increased bleeding or mortality.<sup>201</sup> They found that restarting warfarin after 7 days was associated with a lower risk of thromboembolism and mortality without an increased risk of rebleeding.

More recently, Sengupta et al (2015) conducted a prospective observational study of 197 patients on anticoagulation presenting with GI bleeding.<sup>202</sup> At 90 days of follow-up, anticoagulation continuation at hospital discharge was associated with a significantly lower risk of thrombotic episodes (hazard ratio [HR]=0.121,  $p = 0.03$ ) which was most pronounced in patients with underlying malignancy. There was a nonsignificant trend towards increased rebleeding (HR=2.17,  $p = 0.10$ ), as well as a trend toward decreased mortality (HR 0.63,  $p = 0.40$ ) in patients who were restarted on anticoagulation upon discharge.

Based on limited evidence, current European Society of Gastrointestinal Endoscopy guidelines suggest that resumption of anticoagulation be considered in patients between 7 to 14 days after an episode of GI bleeding. Earlier resumption of anticoagulation may be considered in patients with a low risk of rebleeding and in those in whom the interruption of anticoagulation for over 1 week could be hazardous, such as those with mechanical heart valves, high CHADS2 scores, known thrombotic disorders, or recent thromboembolism.<sup>193,194</sup> Individual patient factors must be considered and consultation with a cardiologist, hematologist, and/or neurologist is often warranted.<sup>195</sup>

#### BOX 14.1 Considerations for Early Reintroduction of Anticoagulation After UGIB

##### Factors That Favor Early Reintroduction of Anticoagulation

- Patient has a high CHADS2 or CHADS-VASC score
- Ulcer or lesion with low-risk of rebleeding (e.g., Forrest IIC or III)
- Successful hemostasis on initial endoscopy with low likelihood of rebleeding
- Patient has normal platelet number and function
- No additional risk factors for bleeding (i.e., no anti-platelets or NSAIDs)
- Patient is clinically stable with no evidence of ongoing bleeding after endoscopy
- Close observation and follow-up is possible after restarting anticoagulation
- Patient has sufficient hemoglobin reserve in case of rebleeding
- Patient has adequate clearance of the anticoagulant (i.e., no renal/liver failure)
- There are no concomitant medications that could interfere with anticoagulant drug levels

Data from Desai J, Kolb JM, Weitz JI, Aisenberg J: Gastrointestinal bleeding with the new oral anticoagulants—defining the issues and the management strategies. *Thromb Haemost* 110(2):205–212, 2013.

Reintroduction of direct-acting oral anticoagulants is a particular issue because of the rapid onset of systemic anticoagulation (often within hours of the first dose), as well as the current paucity of reversal agents in cases of rebleeding.<sup>196,197</sup> A 2013 review article provided practical algorithms for management of anticoagulation in patients with GI bleeding and outlined various factors that can contribute to the decision of restarting anticoagulation (Box 14.1).<sup>197</sup>

#### HELICOBACTER PYLORI

All patients with NVUGIB due to erosions or ulcers should be tested for infection with *H. pylori*, which is one of the principal causes of bleeding ulcers. Without eradication, ulcer relapse and subsequent rebleeding is especially high in these patients.<sup>198,199</sup> Several different testing methods are available including urea-breath testing, histological tests, and serology.<sup>200,201</sup> Testing for *H. pylori* should be performed during the acute UGIB episode and treatment should immediately follow a positive test result.<sup>202</sup> A second test should be performed if an initial one during the acute UGIB episode is negative because false negative rates are high in the acute setting (up to 55%).<sup>203</sup> Real-time polymerase chain reaction (PCR) might improve *H. pylori* detection in patients with peptic ulcer bleeding. Real-time PCR testing for a combination of *H. pylori* 16S rRNA and urease A had a sensitivity of 64% and a specificity of 80% in tissue samples that had previously been considered negative by histological testing alone.<sup>204</sup>

After the completion of antibiotic and PPI treatment, a urea-breath test might be the most convenient approach to assess the effectiveness of *H. pylori* eradication treatment, unless repeat endoscopy is indicated, at which time gastric biopsies can be performed. Regardless of the method being used, checking for eradication is mandatory because of the risk of ulcer recurrence with bleeding as mentioned earlier, and because *H. pylori* infection is a major cause of gastric cancer, specifically noncardia gastric cancer.<sup>205,206</sup> In patients with *H. pylori*-associated bleeding ulcers, continuing PPI therapy after *H. pylori* eradication is not required,

unless there persist other ongoing risk factors, including aspirin or NSAID use.

## IRON REPLACEMENT THERAPY

Patients who present with UGIB should have iron studies performed after the acute bleeding episode. Anemic patients and even nonanemic patients with evidence of iron deficiency should be offered iron replacement therapy upon discharge from hospital as it may improve their quality of life and cognitive function.<sup>19,20</sup> In one study, only 16% of anemic patients post UGIB were prescribed oral supplementation upon discharge from hospital.<sup>20</sup> Correcting anemia rapidly after discharge may be crucial in minimizing both mortality risk and the possible need for a transfusion during a rebleeding episode. In a large prospective study, patients discharged after UGIB with hemoglobin values less than 100 g/L had twice the mortality rates when compared to patients with hemoglobin levels greater than 100 g/L.<sup>19</sup>

Intriguingly, current international consensus and American College of Gastroenterology (ACG) guidelines do not discuss the role of iron replacement post UGIB.<sup>21</sup> A 2014 RCT of 97 patients highlighted the importance of iron replacement by comparing intravenous iron, oral iron, and placebo in patients with anemia secondary to NVUGIB.<sup>21</sup> Patients receiving iron therapy had significantly lower rates of anemia (hemoglobin level < 12 g/dL for women and hemoglobin level < 13 g/dL for men) compared to patients receiving placebo at 3 months post UGIB (17% on iron therapy vs. 70% on placebo,  $p < 0.01$ ). Importantly, there was no difference in efficacy between one dose of intravenous iron and 3 months of oral iron replacement, although compliance in patients taking oral iron was only 56%.

The primary limitation to oral iron supplementation seems to be GI tolerability likely attributable to nonabsorbed iron.<sup>21</sup> All iron salts (ferrous sulfate, ferrous fumarate, and ferrous gluconate) demonstrated similar efficacy and side effect profiles in a randomized trial.<sup>21</sup> A certain controlled-release iron preparation (extended-release ferrous sulfate with mucoproteose) has fewer GI side effects than the iron salts according to a large metaanalysis.<sup>21</sup> There are currently no studies evaluating the tolerability of the newer polysaccharide–iron complexes, although previous studies evaluating similar formulations (e.g., ferric-dextrin complex) have not shown any clear benefit.<sup>21</sup>

## VASCULAR LESIONS

### Dieulafoy Lesion

A Dieulafoy lesion is a dilated aberrant submucosal blood vessel that erodes through the overlying epithelium without an associated mucosal ulcer. The caliber of the artery is much larger than usual mucosal capillaries and measures approximately 1 to 3 mm.<sup>21</sup> One study of 109 patients with Dieulafoy lesions found that most lesions were found in the stomach (53%), followed by the duodenum or jejunum (33%) and lastly colon or rectum (13%).<sup>21,22</sup> There have been rare reports of lesions within the esophagus.<sup>22</sup> Dieulafoy lesions cause approximately 1%–2% of NVUGIB.<sup>2</sup> The 90-day mortality rate has been described between 10%–17%.<sup>20,21</sup> There are no clearly defined risk factors for these lesions; however, NSAIDs and cardiovascular risk factors such as hypertension, chronic kidney disease, and diabetes have been implicated.<sup>21,22</sup>

The natural history of Dieulafoy lesions is that of profuse bleeding; recurrent bleeding occurs in approximately 10% of

patients.<sup>21</sup> Initial evaluation with endoscopy can sometimes reveal the culprit vessel during active bleeding episodes. However, the lesion may be missed in up to 70% of patients in between bleeding episodes and, as such, Dieulafoy lesions remain in the differential for recurrent UGIB without a clear source identifiable on endoscopy.<sup>21</sup> Occasionally, a raised nipple or visible vessel can be visualized and treated.<sup>22</sup> More recently, endoscopic ultrasound has been used to confirm the diagnosis. Once a lesion is found and treated, consideration can be given to tattooing to easily relocate the lesion on follow-up endoscopic evaluation. Capsule endoscopy has been found to be useful at detecting small bowel Dieulafoy lesions and can be considered in patients when esophagogastroduodenoscopy and colonoscopy are unrevealing.<sup>23</sup>

Various endoscopic therapies have been studied in the management of patients with Dieulafoy lesions, including epinephrine injections with bipolar probe coagulation, hemoclip, APC, endoscopic band ligation (EBL), and cyanoacrylate injections.<sup>21,22,23,24–28</sup> The choice of specific therapy may be guided by local expertise, endoscopist preference, and the location of the lesion. Endoscopic banding ligation has been associated with ulcer bleeding once the band has fallen off, as well as perforation, especially in the gastric fundus, small bowel and right colon.<sup>22</sup> One small study of 9 patients found no difference in outcomes using either hemoclips or EBL in the management of patients with bleeding duodenal Dieulafoy lesions.<sup>23</sup> An older observational study suggested that band ligation may be superior to injection therapy.<sup>23</sup>

Some studies have shown that Doppler ultrasound can be considered to confirm ablation of the culprit vessel as a method to prevent rebleeding.<sup>21</sup> Newer therapeutic techniques using endoscopic-ultrasound guidance report more targeted therapy.<sup>23,25,26</sup> For recurrent bleeding refractory to endoscopic therapy, embolization or surgery may be required.<sup>23,25,26</sup>

### Angiodysplasia

Angiodysplastic lesions appear as flat, cherry-red lesions with a fern-like pattern of ectatic blood vessels radiating from a central vessel (Fig. 14.10). These lesions in the stomach and small bowel may be the source of bleeding in 3%–5% of patients presenting

**FIG 14.10** Example of angiodysplastic lesion of the stomach.

**FIG 14.11** **A**, Gastric antral vascular ectasia **B**, treated with argon plasma coagulation.

with UGIB.<sup>236</sup> More commonly, however, these patients will often present with occult GI bleeding and iron deficiency anemia.<sup>237</sup> The diagnosis is usually made on endoscopy, but can also be made using capsule enterography, computed tomography (CT) enterography, or conventional angiography. There are several risk factors that have been implicated in developing angiodysplastic lesions including chronic kidney disease, von Willebrand disease, aortic stenosis, and left-ventricular assist devices.<sup>238–241</sup>

Several endoscopic modalities have proven effective at controlling bleeding angiodysplastic lesions, including APC, bipolar electrocautery, and hemoclips.<sup>234,242</sup> The most widely used method seems to be APC due to its ease-of-use and presumed safety profile. One study found that submucosal injection of normal saline prior to treatment with APC significantly reduced the risk of tissue injury. Although initial therapy is effective, rebleeding rates are reported at 36% at 22 months.<sup>243</sup>

### Gastric Antral Vascular Ectasia (GAVE)

GAVE, also known as "watermelon stomach," has a characteristic appearance of longitudinal rows of flat and reddish spots.<sup>244</sup> These lesions tend to present more often with occult GI bleeding and iron deficiency anemia. GAVE has been associated with female gender, older age (> 70 years old), systemic sclerosis, and cirrhosis.<sup>245,246</sup> The diagnosis is made endoscopically and can be confirmed with biopsy, endoscopic ultrasound, or CT scan.<sup>247</sup>

Endoscopic management options are identical to other vascular lesions and include: APC, bipolar probe, heater probe, cryotherapy, radiofrequency ablation, and EBL (Fig. 14.11).<sup>242,248–251</sup> A systematic review found that patients with GAVE treated with EBL have fewer episodes of rebleeding (8%) compared to those treated with APC (68%,  $p = 0.01$ ). Importantly, there is no evidence that portal decompression with a transjugular intrahepatic porto-systemic shunt (TIPS) procedure provides any reduction in bleeding.<sup>252</sup> For bleeding refractory to endoscopic management, antrectomy has been shown to prevent rebleeding.<sup>253</sup>

### MALLORY-WEISS TEARS

#### Epidemiology and Risk Factors

MWT account for approximately 3%–10% of NVUGIB.<sup>154–156</sup> MWT was first described in 1929 as a linear mucosal laceration of

the distal esophagus often including the gastroesophageal junction and upper part of the stomach.<sup>257</sup> The mechanism responsible for the tear is thought to be rapid propulsion of the gastric cardia into the thoracic cavity through the hiatus, most commonly due to vomiting or retching.<sup>258</sup> The most cited risk factors for a MWT include male gender, age 30 to 50, hiatal hernia, and alcohol use. Alcohol intake has been found to be a contributing factor in 44% of patients presenting with a tear and hiatal hernia is present in 40% to 100% of patients.<sup>259,260</sup> Other factors that may be associated with tears include: severe coughing, pregnancy, heavy lifting or straining, hiccupping, and colonic lavage with polyethylene glycol.<sup>254,259–262</sup> MWT has been described as a rare complication of esophagogastroduodenoscopy and transesophageal echocardiography.<sup>261,263,264</sup> One prospective study of 281 patients found that 30-day mortality was equivalent between MWT and peptic ulcer disease (5.3% vs. 4.6%,  $p = 0.578$ ).<sup>265</sup>

#### Risk Stratification

As the diagnosis of MWT is made endoscopically, initial management is identical to that of all NVUGIB (described in Fig. 14.1). Aspects on clinical history, including retching prior to hematemesis, or other risk factors as mentioned earlier, may increase the likelihood of a tear. Physical examination should be performed to look for signs of crepitus over the chest suggestive of subcutaneous emphysema as a result of an associated (Boerhaave's syndrome) esophageal perforation.<sup>258</sup> A chest x-ray should be performed in all patients to exclude free air under the diaphragm (suggesting a perforation), a pneumomediastinum, or a pneumothorax.<sup>257–270</sup> If there is any concern of possible esophageal rupture, urgent surgical consultation is needed and additional imaging may be required. One retrospective study of 38 patients found that the GBS could be used to predict outcome in patients with MWT.<sup>271</sup> Specifically, they noted that patients with a GBS score less than 6 did not require endoscopic intervention or blood transfusion. Of the patients with a GBS score of 6 or higher, 39% required endoscopic intervention and 74% required a blood transfusion. Recent reports (2016, 2015) describe successful closure of a full thickness tear using an over-the-scope clip and an uncovered metal stent.<sup>272,273</sup> Rebleeding rates from MWT have been reported as 5%–10% depending on various clinical factors including any bleeding diathesis.<sup>262</sup>

### Endoscopic Stigmata

Endoscopic stigmata that predict a high risk of rebleeding in peptic ulcer disease (i.e., Forrest classification) do not apply to MWT. Kim et al (2005) reviewed 159 patients with a MWT with a rebleeding rate of 10.7% of patients; the greatest predictor of rebleeding was active bleeding at time of endoscopy (OR 9.89),<sup>274</sup> whereas another study of 76 patients with MWT suggested that neither a visible vessel nor an adherent clot are associated with rebleeding.<sup>275</sup> As a result, current guidelines suggest that endoscopic therapy be reserved for an actively bleeding MWT and not performed for nonbleeding lesions, including those with visible vessels or adherent clots.<sup>1</sup> In all patients, high-dose PPI therapy is recommended after endoscopic evaluation, although the timing and route of delivery have not been well studied. Extra caution should be taken in patients with coagulopathy, liver disease, and those with hemodynamic instability or transfusion requirements while in hospital.

### Endoscopic Therapy

There are several effective options for endoscopic management of bleeding secondary to a MWT including: injection therapy, hemoclip, electrocoagulation, APC, and EBL.<sup>276</sup> Epinephrine injection by itself may be effective at controlling initial bleeding but has been associated with higher rebleeding rates when compared to combination therapy.<sup>277,278</sup> EBL and hemoclip placement have both proven to be highly effective therapies for MWT.<sup>279</sup> Hemoclip placement can be challenging within the esophagus, especially at the gastroesophageal (GE) junction. EBL, on the other hand, may be somewhat easier to deploy.

One RCT of 41 patients found no significant difference between EBL and hemoclip plus injection in terms of rebleeding rates, need for transfusion, or duration of hospital stay.<sup>280</sup> Another RCT of 56 patients compared EBL and hemoclip plus epinephrine for a bleeding MWT and found that recurrent bleeding was significantly higher in the hemoclip plus injection group compared to the EBL group (18% vs. 0%,  $p = 0.02$ ).<sup>281</sup> It was suspected that injecting with epinephrine prior to deploying the clips led to tissue edema, which perhaps increased the likelihood of clip

detachment. It is therefore suggested that epinephrine injection be administered after the clip has been put in place. Endoscopic electrocoagulation and APC have also been shown to be effective treatments, although both therapies can cause tissue injury, possibly leading to perforation of the esophageal wall.<sup>276</sup>

Overall, clinicians should tailor their choice of endoscopic therapy to their patient, as well as their experience and skillset. If endoscopic therapy fails to control the bleeding, urgent referral should be made for either angiography-guided embolization or surgery.<sup>276</sup> Certainly, urgent surgical referral must be made if esophageal perforation is suspected at any time.

### MALIGNANT BLEEDING

Roughly 1%–5% of all UGIB is caused by either primary GI malignancy or metastatic disease.<sup>282–284</sup> Moreover, UGIB is often the initial presentation in patients with various GI malignancies. Similar to patients with nonmalignancy related bleeding, endoscopy is usually performed within 24 hours in these patients and various modalities including epinephrine or alcohol injections, endoscopic clipping, APC, and bipolar electrocoagulation are often used to control bleeding.<sup>185–287</sup> Compared to peptic ulcer bleeding, however, rates of rebleeding, surgery, and mortality are much higher in patients with malignant bleeding.<sup>282</sup> Indeed, patients with malignancy related bleeding will often require chemotherapy, radiation, interventional radiologic procedures, or surgery to control bleeding.<sup>285</sup> One retrospective study noted rebleeding rates of 49% in patients with UGIB related to malignancy.<sup>281,288</sup>

Studies have found some success at initial endoscopic management with Tc-325 hemostatic powder as it is a noncontact approach that will not traumatize the friable malignant tissue and can be applied to a broad surface area with multiple bleeding points, as is often the case (Fig. 14.12).<sup>188</sup> Although this hemostatic powder can be effective at managing acute malignant bleeding, the powder washes off after approximately 24 hours.<sup>287</sup> Based on uncontrolled studies<sup>188</sup> the powder may be effective at temporarily managing UGIB while other modalities such as radiation, interventional radiologic procedures, or surgery are

**FIG 14.12** **A**, Gastric adenocarcinoma with active oozing **B**, treated with Tc-325 hemostatic powder.

being considered; some patients have experienced prolonged bleed-free episodes. Considering how difficult initial endoscopic management of malignant UGIB can be, and the high rate of recurrent bleeding, gastroenterologists must consider using all options within their armamentarium when faced with a patient with malignant UGIB. The exact role of Tc-325 and other hemostatic powders in malignant bleeding is unknown and awaits results from controlled trials.

## COMPLICATIONS OF ENDOSCOPIC THERAPY

There are several potential complications with all endoscopic therapies and the benefits of each procedure should be carefully weighed against its associated risks.<sup>289</sup> Informed consent must be obtained from the patient or substitute decision maker prior to any procedure.<sup>290–292</sup> Procedural sedation and cardiopulmonary complications including cardiac or respiratory arrest, angina or myocardial infarction, hypotension, hypoxia, and aspiration pneumonia are a few of the many potential complications related to sedation.<sup>293–295</sup> Consideration must always be given to the use of anesthesia and airway protection prior to any procedure, especially in patients with comorbidities such as obstructive sleep apnea or known cardiovascular disease.<sup>296</sup>

One 2016 metaanalysis found that endoscopy performed shortly after an acute coronary syndrome (in most cases, an EGD for bleeding indications) was associated with a higher complication rate and mortality rate; thus, extra care should be taken in deciding the optimal time for endoscopy in this subgroup of patients.<sup>297</sup> Ongoing monitoring and assessment is required before, during, and after the procedure.<sup>296,297</sup> Reversal agents and resuscitation equipment should also be readily available in case of complications.<sup>298</sup>

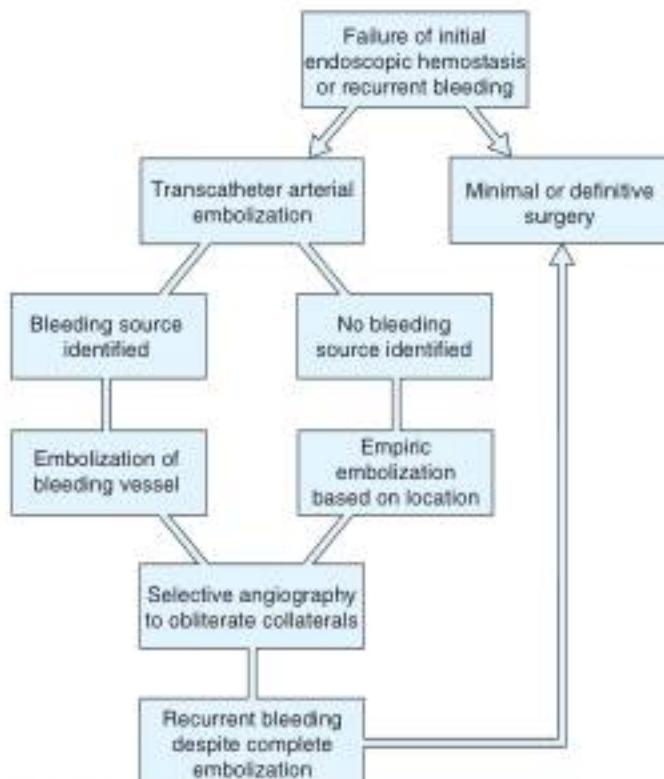

## FAILURE OF ENDOSCOPIC THERAPY

Despite initial resuscitation, medical management, and endoscopic therapy a subset of patients will have recurrent bleeding requiring additional interventions. A management algorithm was recently proposed and is shown in slightly modified version in Fig. 14.13.

## TRANSCATHERETAL ARTERIAL EMBOLIZATION

Embolization is a safe and effective alternative to surgery when endoscopic therapy has failed to control the source of UGIB.<sup>299</sup> By itself, angiography can be used to locate the site of bleeding in the context of massive UGIB whereby endoscopic visualization is limited.<sup>300</sup> If active extravasation of blood is noted, which occurs in approximately 40% of cases, directed embolization can be performed to treat the underlying bleeding vessel.<sup>301,302</sup> If no culprit vessel is identified on angiography, empiric embolization towards a suspected location can be performed as well.<sup>303–305</sup> One study showed that endoscopic clips placed at the time of the failed therapeutic endoscopy near the bleeding site can be helpful in localizing the target location for empiric embolization.<sup>303</sup>

The technical success of embolization ranges between 60% and 100% and the clinical success ranges between 69% and 99%.<sup>301,306,307</sup> The most common reason for ongoing bleeding after embolization is a lesion being fed by the gastroduodenal artery, which often has several collaterals that can continue bleeding despite initial embolization. One study of 60 patients found that 15 of the 16 patients who had rebleeding after initial

**FIG 14.13** Algorithm for failure of initial endoscopic hemostasis or recurrent bleeding. (Modified from Lu Y, Loffroy R, Lau JY, Barkun A: Multidisciplinary management strategies for acute nonvariceal upper gastrointestinal bleeding. *Br J Surg* 101(1):e34–e50, 2014.)

embolization had so due to ongoing bleeding from the collaterals of the gastroduodenal artery.<sup>305</sup>

Immediate complications of angiography include infection or bleeding from the vascular access site, as well as dissection of the target vessel.<sup>308</sup> Other worrisome complications include bowel ischemia and perforation, which have now been minimized by more precise embolization and newer imaging techniques.<sup>309</sup> In a large case series, approximately 9% of patients had minor or major complications including intestinal ischemia, perforation, and duodenal stenosis.<sup>308,310</sup>

Current guidelines suggest that embolization be considered after two endoscopic attempts have been made to control the bleeding.<sup>311</sup> RCTs have shown that percutaneous embolization is efficacious and has a lower mortality rate than surgery.<sup>310,311</sup> Occasionally, for patients found to have large ulcers or those with unfavorable locations for endoscopic therapy, embolization may be used as second-line therapy instead of a repeat endoscopy. Some studies have even suggested a role for prophylactic embolization to prevent recurrent bleeding in certain patients with high-risk endoscopic features.<sup>312–314</sup> In general, embolization is preferred over surgery due to its equivalent efficacy and favorable safety profile.<sup>312</sup> The precise role of technique of embolization will continue to be defined as studies address important clinical dilemmas.

## EMERGENCY SURGERY

The need for emergency surgery for bleeding peptic ulcers has decreased significantly over the past 2 decades.<sup>315</sup> In the United

Kingdom, the rate of surgery for peptic ulcer disease decreased from 8% in 1993 to 2% in 2006.<sup>32,33</sup> In the United States, the rate of emergency ulcer surgery has decreased by over 21%.<sup>31</sup> The reasons for the decreased need for surgery include the routine use of PPI therapy, as well as the improvements in endoscopic management.<sup>34,35</sup> Surgical intervention, however, is still needed in certain cases of refractory UGIB whereby endoscopic and radiologic procedures are either not possible or unsuccessful.<sup>32</sup> As the risks of surgical intervention are greater than the risks of either endoscopic or radiologic intervention, surgery is only reserved for those who have failed other less-invasive alternatives.

Surgical options include simple intraluminal ligature or plication alone, which is less invasive, or the more conventional surgery, which includes ulcer excision with either vagotomy and pyloroplasty or a partial or total gastrectomy.<sup>32</sup> Although several randomized trials have suggested a lower rebleeding risk with a partial or complete gastrectomy, mortality rates are no different than with the less invasive surgical options.<sup>32,33</sup>

Overall, surgery remains a valuable option for certain patients but should not be considered unless there is ongoing bleeding after failing both endoscopic and radiologic therapies. In certain patients with massive hemorrhage or endoscopic findings suggestive of high-risk lesions that may not be amenable to endoscopic therapy, early surgical referral may be considered.

## FUTURE DIRECTIONS FOR ENDOSCOPIC THERAPY

### Over-the-Scope Clip

Novel endoscopic techniques continue to be developed to better manage patients with NVUGIB.<sup>36</sup> One case series of 9 patients used an over-the-scope clip to manage patients with refractory UGIB after initial endoscopic therapies were used.<sup>37</sup> Chan et al (2014) found that over-the-scope clip could be deployed successfully in all patients and clinical bleeding was stopped in 77% (7/9) of patients. Another retrospective review of 14 patients with recurrent UGIB despite endoscopic therapy found that an over-the-scope clip was successful in 86% (12/14) of patients at preventing further bleeding with no adverse events.<sup>38</sup> Future studies will evaluate this technique as initial therapy for larger, high-risk ulcers, as well as those with recurrent bleeding despite routine endoscopic management.

### Doppler Endoscopic Probe

Newer endoscopic modalities such as a Doppler endoscopic probe have been used to better characterize peptic ulcer rebleeding risk when compared to traditional measures, such as the Forrest classification. Some studies have shown no added benefit of the Doppler probe in the management of patients with UGIB.<sup>39,40</sup> One prospective study of 163 patients with bleeding peptic ulcers found that the Doppler probe was useful in correlating arterial blood flow at the base of the ulcer with subsequent rebleeding rates.<sup>39</sup> They also showed that the Doppler flow seen after endoscopic treatment correlates with rebleeding risk as well. This study suggests that using Doppler in addition to the Forrest classification may have a beneficial effect in identifying patients who are at the highest risk of rebleeding and also as a method of determining whether patients may benefit from additional endoscopic interventions to achieve definitive hemostasis. Future multicenter randomized controlled studies are needed to confirm these findings.

## CONCLUSIONS

The management of NVUGIB begins with resuscitation, risk stratification, and preendoscopic medical management, including prokinetics and PPI therapy. Endoscopy should be performed in all patients within 24 hours, although certain high-risk patients may benefit from earlier endoscopy, whereas other patients who are low-risk may be discharged home with close follow-up. Endoscopic findings and technical expertise will determine which endoscopic modality, if any, will be used for hemostasis, although injection of epinephrine alone is less effective than other approaches. Postendoscopic management is based on the etiology and endoscopic appearance of the lesion, and patients with high-risk lesions should receive intravenous PPI therapy for 3 days before being discharged on an oral regimen. Any reversible risk factors should be addressed, including anti-platelets, NSAIDs, anticoagulation, and *H. pylori*. Patients with recurrent bleeding episodes should undergo repeat endoscopy followed by percutaneous embolization and surgery, if needed. Future research will continue to identify the role of emerging therapies, including hemostatic powders, in view of their continuing to improve the outcomes of patients presenting with NVUGIB.

## INTRODUCTION

Portal hypertension is defined by a pathologic increase in portal pressure in which the pressure gradient between the portal vein and inferior vena cava (the portal pressure gradient, PPG) is increased above the upper normal limit of 5 mm Hg.<sup>1</sup> Portal hypertension becomes clinically significant when the PPG increases above the threshold of 10 mm Hg (formation of varices)<sup>2</sup> or 12 mm Hg (variceal bleeding, ascites).<sup>2,3</sup>

Acute variceal bleeding (AVB) is the most dreaded complication of portal hypertension because, even though mortality rates have decreased due to improvement in general management, medical treatment, and endoscopic therapy, mortality is still approximately 15%. Moreover, variceal bleeding leads to deterioration in liver function and can trigger other complications of cirrhosis such as bacterial infections, hepatic encephalopathy (HE), or hepatorenal syndrome. Therapy to prevent rebleeding (secondary prophylaxis) is mandatory given that patients surviving a variceal bleeding episode have a very high risk of rebleeding, which is associated with mortality as high as that of the first bleed.

## NATURAL HISTORY OF VARICES IN CIRRHOSIS

The natural history of cirrhosis is considered to be a progression from compensated cirrhosis to decompensated cirrhosis. Compensated cirrhosis is defined as the absence of jaundice, variceal hemorrhage (VH), ascites, and HE. On the other hand, decompensated cirrhosis is defined as the presence of one of these features. The transition from compensated to decompensated cirrhosis occurs at a rate of 5% to 7% per year.<sup>4,5</sup> The development

of portal hypertension directly leads to the formation of portal-systemic collaterals such as esophageal and gastric varices and represents a key stage in this natural history of cirrhosis.

When cirrhosis is diagnosed, varices are present in approximately 30% to 40% of compensated patients and in 60% of those with decompensated cirrhosis.<sup>6</sup> The annual incidence of new varices is approximately 5% to 10%;<sup>7</sup> these initially develop as small varices and gradually dilate at a rate of 5% per year. The factor that has been most consistently associated with variceal progression is baseline Child-Pugh or its worsening during follow-up.<sup>8</sup> Variceal bleeding usually occurs late in the natural history of portal hypertension and in order for varices to bleed the hepatic venous pressure gradient (HVPG) must rise above 12 mm Hg.<sup>2,9</sup> Certain characteristics, such as the severity of liver disease, the size of the varix, and the presence of red wale marks (specially on thin areas of the variceal wall), place the varices at higher risk of bleeding, which can occur with an incidence of 4% to 15% per year.<sup>6,10,11</sup> The risk of bleeding is very low (between 1% and 2%) in patients without varices at the first examination, and increases to approximately 5% per year in those with small varices and to 15% per year if medium or large varices are present at diagnosis.<sup>12</sup>

## PREVENTION OF FIRST BLEEDING FROM ESOPHAGEAL VARICES

### Screening for Esophageal Varices

Until recently, the current consensus was that every cirrhotic patient should be endoscopically screened for varices at the time of diagnosis<sup>13</sup> to detect those requiring prophylactic treatment.

### Abstract

Variceal bleeding is one of the most severe complications of liver cirrhosis. When cirrhosis is diagnosed, varices are present in approximately 30% to 40% of compensated patients and in 60% of those who present with ascites. Once varices have been diagnosed, the overall incidence of variceal bleeding is 25% within two years. Variceal size is the most useful predictor for variceal bleeding; other predictors being the severity of liver dysfunction (Child-Pugh classification) and the presence of red wale marks on the variceal wall. When a patient presents with acute variceal bleeding, appropriate management with initial general measures such as resuscitation (airway, breathing, and circulation), a restrictive transfusion policy, antibiotic prophylaxis, pharmacological therapy with vasoconstrictors, and endoscopic therapy with endoscopic band ligation is mandatory. After bleeding has been controlled, combination therapy with nonselective  $\beta$ -blockers (NSBBs) and endoscopic band ligation should be used to prevent rebleeding. In patients at high risk of treatment failure identified early after admission, the placement of a preemptive TIPS (transjugular intrahepatic portosystemic shunt) improves control of bleeding, prevents rebleeding, reduces mortality, and should be the treatment of choice if no contraindications are present. When initial endoscopic therapy fails, rescue therapies such as Sengstaken-Blakemore tubes and fully covered self-expandable esophageal metal stents may be required as a bridge toward the definitive treatment with TIPS. Regarding gastric variceal bleeding, data is limited. In acute cardiofundal variceal bleeding, vasoactive agents, together with cyanoacrylate (CYA) injection, seem to be the treatment of choice. Further CA injections and/or NSBB may be used to prevent rebleeding. TIPS, or balloon-occluded retrograde transvenous obliteration when TIPS is contraindicated, may be used as a rescue therapy.

acute variceal bleeding

However, the introduction of transient elastography (Fibroscan) of the liver has changed this scenario in some patients. Fibroscan is used to estimate the degree of liver fibrosis but also to determine if patients are at risk of having varices and portal hypertension. This has been extensively studied and validated in patients with cirrhosis due to hepatitis C (HCV); current guidelines suggest that patients with HCV and elastography values of stiffness less than 20 kPa and a platelet count over 150,000 could avoid screening endoscopy because the risk of having varices is extremely low.<sup>14</sup>

In patients without varices on initial endoscopy, follow-up evaluation should be performed after 2 to 3 years (2 if there is a deterioration in liver function).<sup>14</sup> In patients with small varices, a follow-up endoscopy should be performed every 1 to 2 years to check for a possible increase in size, based on an expected 10% to 15% per year rate of progression of small to large varices. This time interval should be shortened in cases of clinical decompensation. Primary prophylaxis with nonselective β-blockers (NSBBs, propranolol, nadolol, carvedilol) or endoscopic band ligation (EBL) must be initiated when the patient develops medium to large varices or small varices with red wale signs in those with Child-Pugh class C cirrhosis.<sup>15</sup> No follow-up endoscopy is needed once NSBBs are started, but once initiated, NSBBs should be maintained through the patient's life. Although still not discussed in guidelines, there is recent evidence (2016) suggesting that carvedilol might delay the progression of small to large esophageal varices (EVs).<sup>16</sup>

### **Nonselective β-Blockers Versus Endoscopic Banding**

#### **Ligation for Primary Prophylaxis**

NSBBs are effective in the prevention of variceal bleeding. These drugs reduce portal pressure by decreasing portal venous inflow through vasoconstriction of the splanchnic circulation and by decreasing cardiac output.<sup>17</sup> A reduction in HVPG to 12 mm Hg or less, or 20% or less from baseline, protects from VH<sup>17,18</sup> and also decreases the incidence of clinical decompensation.<sup>19</sup> NSBB side effects (hypotension, fatigue, weakness) can be managed by adjusting the dose. However, up to 20% of patients may have absolute or relative contraindications.

Propranolol is typically started at 20 mg twice daily and nadolol at 40 mg once a day. These drugs are given in a stepwise fashion, increasing the dose until it is maximally tolerated or the resting heart rate is between 50 and 60 beats/min. Carvedilol is more effective than propranolol in reducing HVPG<sup>18-21</sup> through an anti α-adrenergic activity and a mildly vasodilating effect. Carvedilol is started with 6.25 mg once a day and afterwards the dose is increased to 6.5 mg twice a day (higher doses may not further decrease portal pressure, yet may increase the risk of arterial hypotension). Indirect data suggests that carvedilol is more effective than propranolol/nadolol in primary prophylaxis, although this has not been adequately studied in head-to-head clinical trials.

Variceal ligation is performed every 3 to 4 weeks until variceal eradication is achieved, which typically occurs after 2 to 4 sessions. Eradication is defined by either the disappearance of the varices or the impossibility of grasping and banding them with the ligator. Meta-analyses of randomized controlled trials (RCTs) of β-blockers versus band ligation indicate that ligation is associated with a lower incidence of first VH without differences in mortality.<sup>22,23</sup> Nonetheless, endoscopic ligation requires several sessions and may be associated with important side effects, such as bleeding from postligation ulcers. Although the choice of

β-blockers or endoscopic therapy should be made depending on the local resources, availability of experienced endoscopists, patient preference, side effects, and contraindications, a reasonable approach is to begin with β-blockers if there are no contraindications because they are inexpensive, easy to use, and relatively safe.<sup>25</sup> Those patients who develop side effects or have contraindications to β-blockers should then be offered endoscopic variceal band ligation. If the patient tolerates NSBBs, no follow-up endoscopy is needed. In those that undergo EBL and for whom varices are eradicated, follow-up endoscopies approximately 3 months after the complete eradication should be performed and varices should be reeradicated upon recurrence.

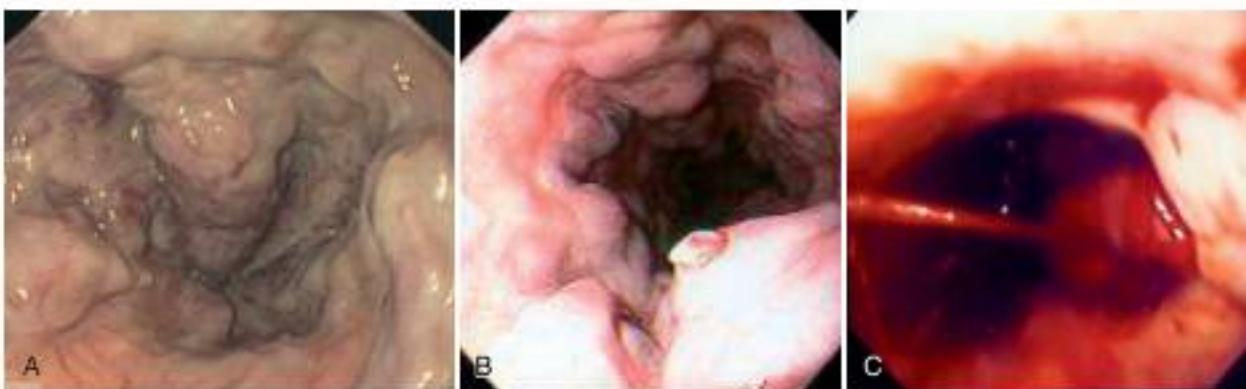

All randomized studies and meta-analyses comparing the combination of NSBB plus EBL versus EBL alone in primary prophylaxis had failed to demonstrate a clear benefit from combination therapy, with a predicted higher number of adverse events in the combination therapy group<sup>26</sup> not supporting the use of combination therapy for primary prophylaxis. However, a 2017 study has challenged this recommendation, suggesting that the combination therapy of NSBB and EBL may be more effective in primary prophylaxis than NSBB alone or EBL alone for the prevention of acute variceal bleeding, although with similar mortality rates at 2 years. Until more data is available, it is wise to follow the current guidelines of using either NSBB or EBL, but not in combination.<sup>27</sup>

## **GENERAL MANAGEMENT OF ACUTE VARICEAL BLEEDING (AVB)**

Ruptured EV cause 80% of all upper gastrointestinal bleeding episodes in patients with portal hypertension.<sup>28</sup> Diagnosis is established at emergency endoscopy based on observing one of the following: (1) active bleeding from a varix (observation of blood spurting or oozing from the varix); (2) white nippel or clot adherent to a varix; or (3) presence of varices without other potential sources of bleeding (Fig. 15.1). Endoscopy should be performed within the first 12 hours of admission, especially in patients with hematemesis or hemodynamic instability.

AVB should be managed in an intensive care setting. The initial ABCs (airway, breathing, circulation) of resuscitation should be applied with the aim of maintaining aerobic metabolism and restoring an appropriate oxygen transport to the tissues. At least two large bore venous accesses should be placed on admission, as they can be necessary for rapid administration of volume during initial resuscitation. An airway should be immediately secured, and endotracheal intubation is mandatory before endoscopy if there is any concern about the safety of the airway, especially in encephalopathic or actively bleeding patients, as they are at risk of bronchoaspiration of gastric content and blood; this risk is further exacerbated by endoscopic procedures.<sup>28,29</sup>

Avoiding prolonged hypotension is particularly important to prevent further complications such as renal failure and ischemic hepatitis, which are associated with increased risk of rebleeding and death,<sup>30</sup> and therefore blood volume replacement with plasma expanders must be used, aiming at maintaining a mean arterial pressure of at least 65 mm Hg. However, overexpansion must also be avoided as it may induce rebound increases in portal pressure and facilitate rebleeding. Therefore, a delicate fluid balance is needed. In fact, an RCT showed that a restrictive transfusion strategy in which patients were only transfused if hemoglobin levels dropped below 7 g/dL improved survival in

**FIG 15.1** Endoscopic view of **A**, a large varix with red wale marks; **B**, a large varix with a white nipple sign; **C**, an actively bleeding (spurting) esophageal varix in a patient with cirrhosis.

Child-Pugh A and B patients, except in patients with shock, ongoing bleeding, or ischemic heart disease.<sup>32</sup>

As mentioned earlier, the main associated complications of AVB are bacterial infections, HE, and impaired renal function. Infections may be both a consequence and a precipitating event leading to AVB. Antibiotic treatment significantly decreases the risk of rebleeding and improves survival.<sup>33</sup> In most cases, either norfloxacin 400 mg by mouth twice daily for 7 days or IV ceftriaxone 1 to 2 g/day can be given, although intravenous antibiotics are preferred in those patients with hypovolemic shock and advanced cirrhosis,<sup>34</sup> in hospital settings of high prevalence of quinolone-resistant bacterial infections, and in patients on previous quinolone prophylaxis.<sup>34</sup> Variceal bleeding can trigger HE, mainly because of the intestinal absorption of toxic substances generated from blood proteins. Even though there is no strong data supporting the need of prophylactic treatment, both lactulose and rifaximin should be used to prevent HE.

The rapid implementation of vasoconstrictors and performance of endoscopy should be instituted within the first 12 hours of admission; however this interval can be shortened to 6 hours in those with hematemesis once they are stabilized in a monitored unit.<sup>35</sup>

Finally, it is important to consider if the patient is at high risk for treatment failure, which is known to occur in approximately 15% of patients. Critically, this is the population where mortality-related bleeding concentrates.<sup>36</sup> A multicenter European randomized clinical trial<sup>37</sup> showed that high-risk patients (defined as Child-Pugh C up to 13 points, or Child B plus active bleeding at endoscopy) benefit from a preemptive transjugular intrahepatic portosystemic shunt (TIPS) within 72 hours of admission. This approach markedly decreased rebleeding and mortality without increasing the incidence of HE. Beneficial effects of the use of preemptive TIPS in high-risk patients were confirmed in an observational retrospective study.<sup>38</sup>

## HEMOSTATIC THERAPIES

Initial therapy for acute variceal bleeding is based on the combination of vasoactive drugs with endoscopic therapies.<sup>39</sup> The early use of vasoconstrictors in most cases can initially arrest bleeding, which translates to better visualization at endoscopy. These drugs also reduce rebleeding and improve survival among patients with cirrhosis and AVB.<sup>40–44</sup>

**TABLE 15.1 Vasoconstrictors Used in Acute Variceal Bleeding**

Drug	Dose
Terlipressin	Intravenous bolus 2 mg/4 hr for 24–48 hr then 1 mg/4 hr
Somatostatin	Intravenous bolus 250 mcg followed by infusion of 250–500 µg/hr
Octreotide	Intravenous bolus of 50–100 µg followed by infusion of 50 µg/hr

All drugs are administered for a minimum of 2 days and may be extended for up to 5 days.

## Pharmacological Treatment

The drug selection will depend mainly on local resources as different studies and meta-analysis have not found significant differences in efficacy when comparing the different vasoactive agents.<sup>44</sup> The most commonly used vasoactive drugs are terlipressin, somatostatin, and its analogue (octreotide) (Table 15.1).

Terlipressin is a long-acting derivative of vasopressin that has been shown to effectively control AVB, decrease transfusion requirements, and decrease bleeding-related mortality.<sup>45,46</sup> As soon as variceal bleeding is suspected, terlipressin should be initiated at a dose of 2 mg every 4 hours during the first 24 hours, and it may be maintained for up to 5 days at a dose of 1 mg every 4 hours to prevent rebleeding.<sup>42</sup> As it is a potent vasoconstrictor, terlipressin may be associated with mild adverse events such as abdominal pain, diarrhea, or bradycardia;<sup>47</sup> it can also induce cardiac ischemia and it is therefore contraindicated in patients with known ischemic heart disease.<sup>48</sup> Hyponatremia in varying degrees has been described in patients treated with terlipressin, especially those with preserved liver function, and therefore sodium levels must be monitored.<sup>47</sup>

Somatostatin reduces portal pressure by inducing selective splanchnic vasoconstriction without systemic effects.<sup>49</sup> It is commonly used as an initial bolus of 250 µg followed by a 250 µg/hr or 500 µg/hr infusion that is maintained for 5 days or until the achievement of a 24 hours bleed-free period.<sup>48</sup> The 500 µg/hr dose causes a greater fall in HVPG (13% vs. 6% compared to 250 µg/hr) and seems to have greater clinical efficacy in the

subset of patients with active variceal bleeding at emergent endoscopy.<sup>51</sup>

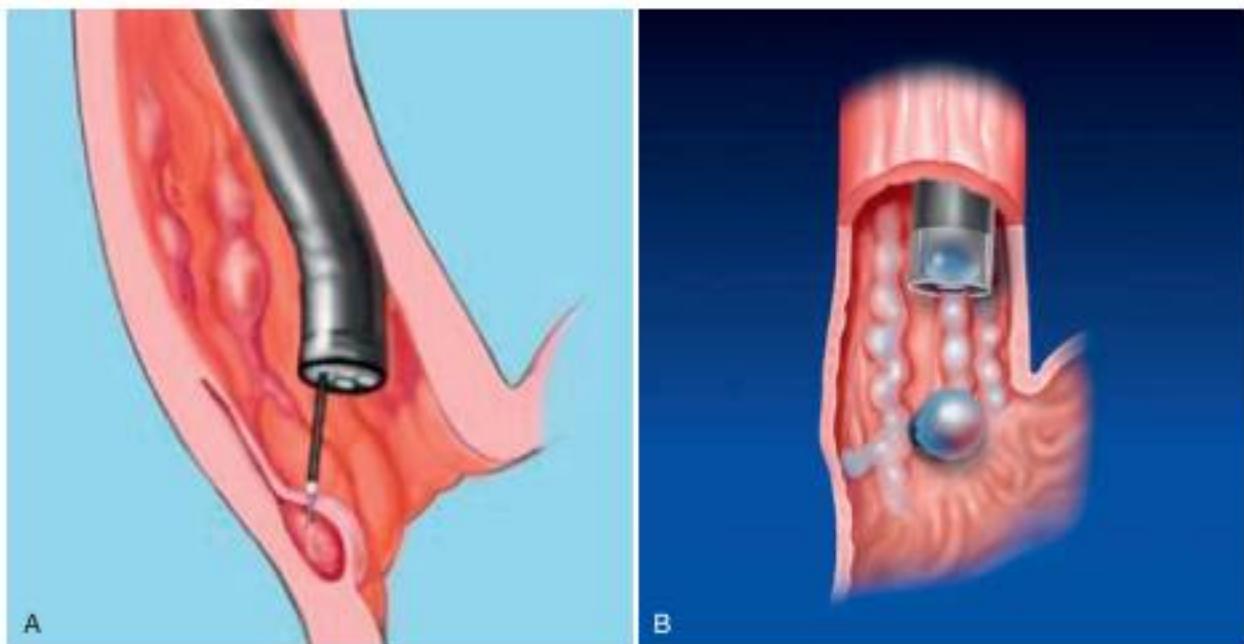

Octreotide is a somatostatin analogue with a longer half-life<sup>51</sup> but similar safety profile than somatostatin. The optimal doses are not well determined, but it is usually given as an initial bolus of 50 to 100 µg, followed by an infusion of 25 or 50 µg/hr.<sup>52</sup> As with somatostatin, therapy can be maintained for 5 days to prevent early rebleeding. Octreotide may improve the results of endoscopic therapy but has uncertain effects if used alone.<sup>51,53</sup>

### Endoscopic Therapy

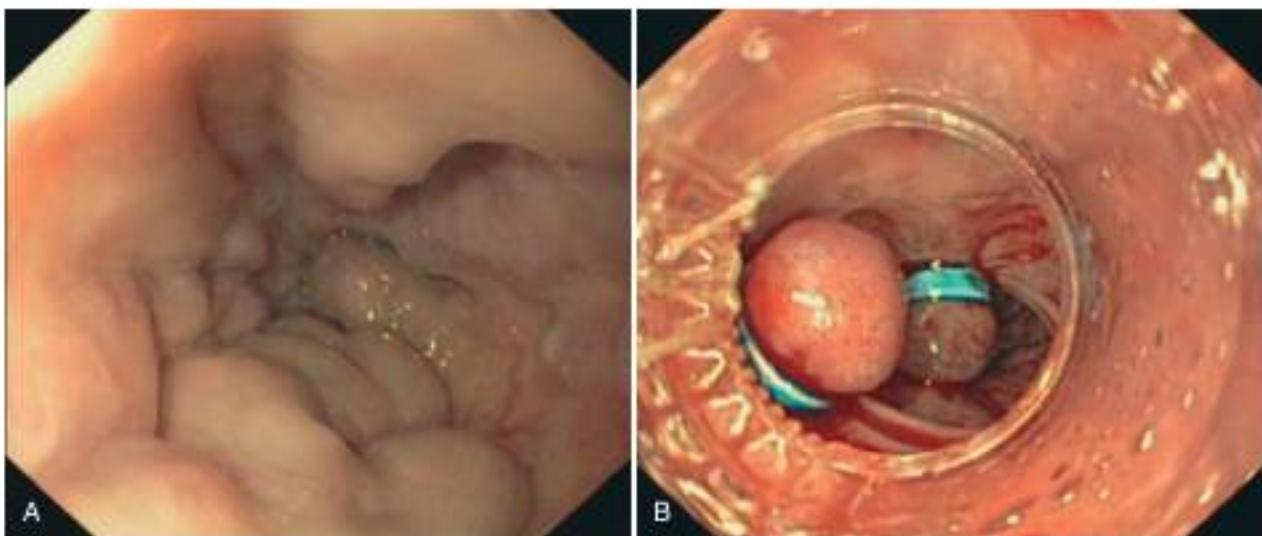

Endoscopy is one of the cornerstones of the management of AVB because it confirms the diagnosis and allows specific therapy during the same session. An important consideration before

considering endoscopy is choosing the type of sedation for the procedure, as patients need to be fully sedated for the procedure to be successful. Intravenous sedation with propofol is a safe and better tolerated option than benzodiazepines (midazolam) plus an opiate (meperidine or fentanyl), which can potentially trigger episodes of minimal HE.<sup>53–55</sup> Endoscopic therapies for varices are effective because they cause obliteration of the varix. The two endoscopic methods available for AVB are endoscopic sclerotherapy (ES) and EBL (Figs. 15.2 and 15.3).

ES consists of the injection of a sclerosing agent (sodium morrhuate [5%], ethanolamine oleate [5%] or polidocanol [1%–2%]) into the variceal lumen or adjacent to it. This causes inflammation and thrombosis, creating a scar over the site of the varix. Although it is easy to perform (only an injection catheter

**FIG 15.2** Two endoscopic methods used for the management of varices: **A**, sclerotherapy and **B**, band ligation.

**FIG 15.3** **A**, Endoscopic view of large varices. **B**, Endoscopic view of successfully placed bands in the distal esophagus.

and the sclerosant are needed) there are a significant number of local and systemic complications, which include esophageal ulcers, strictures, substernal chest pain, fever, dysphagia, and even the development of pleural effusions.<sup>36,37</sup> ES also increases the risk of bacteremia and can predispose one to spontaneous bacterial peritonitis or distal abscesses.<sup>38,39</sup> Other rare complications include perforation, mediastinitis, pericarditis, chylothorax, and esophageal motility disorders.<sup>36,37,40,41</sup>

EBL consists in the placement of several elastic bands (range between 4 to 10) on the varices to occlude the varix and cause thrombosis. Ligation of the varix and the surrounding mucosa eventually leads to necrosis of the mucosa. The bands fall off within 5 to 7 days, leaving a shallow ulcer that heals and subsequently scars. After the index treatment of an episode of AVB, scheduled repeated sessions need to be performed at 3- to 4-week intervals to completely obliterate the varices and reduce the risk of rebleeding.<sup>42</sup>

There are several commercially available multiband devices. They have between 4 and 10 preloaded bands (Fig. 15.4). Beginning the procedure with a 6- or 7-band device will allow for enough bands to be placed in a single session without having to repeatedly intubate the patient with the gastroscope. After the index diagnostic endoscopy is performed in a patient with AVB and the suspected varix is identified, the endoscope is withdrawn and the ligation device is loaded. After the varix is identified, the tip of the scope is pushed toward it and continuous suction applied so the mucosa of the varix fills the cap and causes a "red out" sign; at this point the band can be fired and a click is felt. The red out sign is always required; otherwise the band will inevitably be misfired. Afterwards, the scope should not be advanced distally. Band ligation should always commence in the most distal portion of the esophagus near the gastroesophageal (GE) junction (Video 15.1). Bands are applied in a spiral pattern progressing up the esophagus until all major columns of varices of the lower third of the esophagus (no more than 8 to 10 cm above the GE junction) are banded. If there is a limited view because of ongoing bleeding, an option is to aggressively flush with water, perform suction, and start placing bands at the GE junction. This reduces the heavy bleeding and further bands can be fired afterwards.

The procedure can be associated with adverse events such as transient dysphagia and chest pain, which respond well to analgesics (i.e., liquid acetaminophen), as well as an oral suspension of antacids. A liquid diet should be started the same day

and soft foods the next day. Shallow ulcers at the site of bands are frequent and can bleed in up to 4% of cases.<sup>43</sup> The use of a proton pump inhibitor (i.e., pantoprazole 40 mg/day for 10 days) decreases the size of ulcers but does not prevent them from bleeding.<sup>44</sup> Severe and rare complications such as massive bleeding from ulcers or rarely from variceal rupture, esophageal perforation, esophageal strictures, or altered esophageal motility, may occur with EBL.<sup>45</sup> If a patient bleeds due to an ulcer after EBL, ES may be performed if there is active bleeding or oozing, but this approach is often ineffective. Where available, an option is applying Hemospray (Cook Medical, Winston-Salem, NC) (a hemostatic powder) to the bleeding site. This powder, which is used for nonvariceal gastrointestinal bleeding, seems to be promising as a hemostatic technique for patients with portal gastropathy, variceal bleeding, and bleeding post-EBL ulcers.<sup>46-48</sup>

EBL is highly effective in the control of AVB, with an immediate efficacy in 90% of cases.<sup>49</sup> Several clinical trials and a meta-analysis indicate that EBL is better than ES for all major outcomes, including initial control of bleeding, recurrent bleeding, time to variceal eradication, and survival<sup>50,51</sup>; in addition, it is associated with less adverse events.<sup>52</sup> Therefore, EBL is considered the endoscopic therapy of choice in AVB. Although EBL is preferred over ES for an episode of AVB, in the setting of active hemorrhage or torrential bleeding, EBL may sometimes be difficult to perform due to lack of visibility. Therefore, both techniques are reasonable options in the setting of AVB.

### Prevention of Recurrent Bleeding From Esophageal Varices

The combination of drug therapy with EBL is the recommended strategy for preventing variceal rebleeding.<sup>53,54,55</sup> Recent data suggest that NSBBs are the main drug responsible for the benefit of the combination.<sup>56</sup>

### FAILURE TO CONTROL BLEEDING

During an acute episode of variceal bleeding, approximately 10% to 15% of patients do not respond to the previously mentioned therapies and controlled bleeding is not achieved. In such cases, if the patient is stable, a second therapeutic endoscopy may be performed. However, if this is unsuccessful or there is massive bleeding, the patient should be offered alternate treatment, before the clinical status further deteriorates. Both TIPS and surgical shunts are extremely effective at controlling

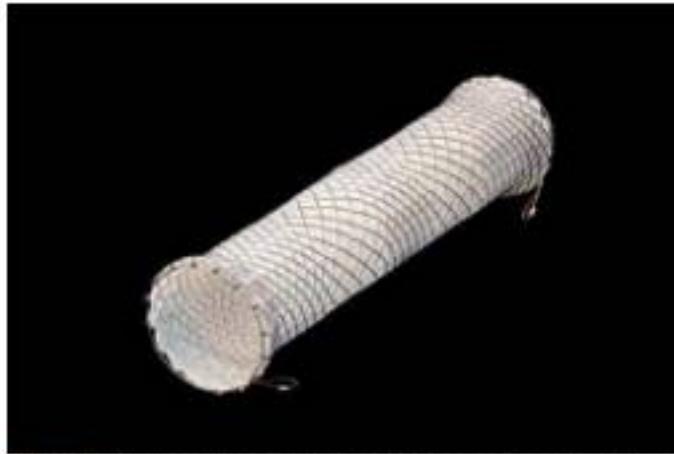

**FIG 15.4** **A**, Band ligator placed on the shaft of the endoscope, the knob is attached to the working channel. **B**, The proximal end of the endoscope has a cap with premounted bands that allows for suction of the varix (in this case a glove is used). **C**, Once the varix is suctioned into the cap, the band is fired and the varix is ligated.

variceal bleeding, although TIPS is the first-choice treatment because most patients requiring rescue treatment have advanced liver disease.<sup>14,73</sup> However, until definitive treatments such as TIPS can be instituted, patients may require temporary placement of balloon tamponade or esophageal stents.

Current guidelines recommend using balloon tamponade only in massive bleeding, as a temporary "bridge" until definitive treatment can be instituted (for a maximum of 24 hours) in an intensive care unit.<sup>79,80</sup> Esophageal balloon tamponade, which is typically performed with a Sengstaken-Blakemore tube, causes hemostasis by direct compression of the bleeding varices. If placed properly, tamponade may provide initial control of bleeding in up to 85% of cases, but rebleeding is observed in 50% of the patients after deflation of the balloon.<sup>81</sup> The most common complications include aspiration pneumonia and esophageal perforation, which may occur in 30% of patients, with a mortality rate of 5% mainly due to perforation.<sup>82</sup> The incidence of complications increases with the duration of tamponade and when tubes are inserted by inexperienced staff. Therefore, tamponade should only be performed by skilled and experienced personnel in intensive care facilities and with special caution in patients with respiratory failure or cardiac arrhythmias. Because of the high risk of aspiration pneumonia, tamponade should be preceded by prophylactic orotracheal intubation.

A safer alternative to balloon tamponade is placing fully covered self-expandable metal stents which act as tamponade mechanism on the esophagus.<sup>83</sup> The main advantages include fewer side effects, ability to maintain enteral feeding, and the possibility to leave the stent in place for 1 week, which allows for stabilization of the patient in order to plan bridge therapies such as TIPS. The SX-Ella Danis stent (135 mm × 25 mm; ELLA-CS, Hradec Kralove, Czech Republic) is a removable, fully covered, self-expanding nitinol metal stent with atraumatic edges specifically designed for AVB (Fig. 15.5). It comes in a ready to use procedure pack that contains all items necessary for its placement. In addition, it has radiopaque markers at both ends

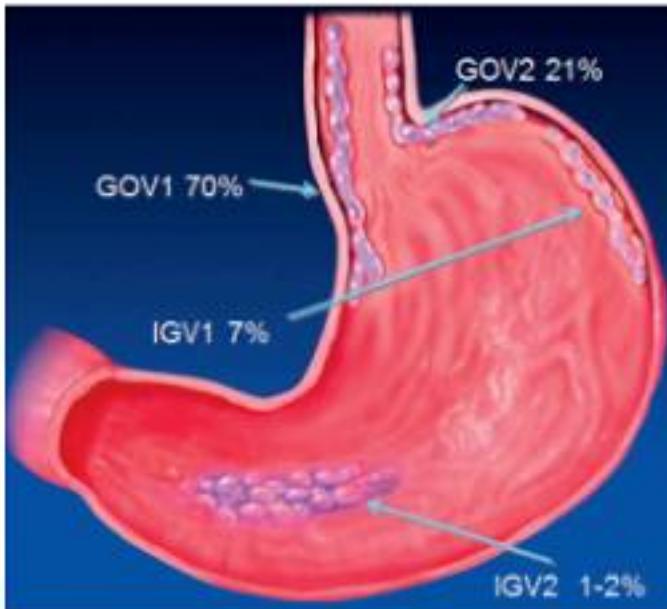

**FIG 15.5** A fully covered, self-expandable esophageal stent can be placed in the esophagus as a rescue therapy in patients in whom variceal bleeding cannot be controlled by endoscopic therapy plus vasoactive drugs. The stent (SX-Ella Danis) is 135 mm long × 25 mm wide and has two threads in the distal and proximal end that allows the stent to be pulled endoscopically. (Courtesy ELLA-CS, Hradec Kralove, Czech Republic.)

and at the midportion for monitoring with plain chest x-rays. The stent can be deployed in the lower esophagus without radiological or endoscopic assistance; however in some cases a prior endoscopy is useful as a means of leaving a rigid guidewire in the stomach, which later aids in placing the premounted stent. The procedure is relatively easy to perform but basic training is needed. The stent can be removed 7 days later endoscopically using an overtube system (Extractor for SX-ELLA Danis stent) without causing trauma to the esophagus.

A 2016 RCT comparing esophageal metal stent versus tamponade by using the Sengstaken-Blakemore balloon in patients with esophageal variceal bleeding refractory to medical and endoscopic treatment showed that success of therapy, defined as survival at day 15 with control of bleeding and without serious adverse events, was more frequent in the stent than in the tamponade group, with similar survival but less serious adverse events. Therefore, these findings favor the use of esophageal stent for refractory variceal bleeding.<sup>81</sup>

## GASTRIC VARICEAL BLEEDING

Gastric varices (GV) are present in approximately 20% of patients with portal hypertension and are the source of 5% to 10% of all upper digestive bleeding episodes in patients with cirrhosis. The classification of GV by Sarin et al (1992) is the most commonly used for risk stratification and management<sup>84</sup> (Fig. 15.6). The most common are gastroesophageal varices type 1 (GOV1): EV extending below the cardia into the lesser curvature (75% of GV). These are usually managed as the EV. GOV type 2 (GOV2)

**FIG 15.6** Sarin's classification is the most commonly used for risk stratification and management of gastric varices. GOV1: EV extend below the cardia into the lesser curvature. GOV type 2 (GOV2) are EV extending into the fundus, isolated GV type 1 (IGV1) are located in the fundus, whereas isolated GV type 2 (IGV2) are located elsewhere in the stomach. EV, esophageal varices; GV, gastric varices; GOV, gastroesophageal varices; IGV, isolated GV.

**FIG 15.7** Endoscopic view of an isolated GV type 1 (IGV1) with stigmata of recent bleeding.

are EV extending into the fundus and account for 21% of GV. Isolated GV type 1 (IGV1) are located in the fundus (7%) (Fig. 15.7), whereas isolated GV type 2 (IGV2) are located elsewhere in the stomach (1%–2%).

The evidence to support management recommendations of GV bleeding is less robust than that for EV, as most data come from retrospective series. Few RCTs are available, and those that are have a small sample size and, in many occasions, no adequate stratification according to the type of GV or presence/severity of liver disease.

#### Prevention of First Hemorrhage From Gastric Varices

There is only one RCT on the primary prevention of gastric VH, including 89 patients with large ( $\geq 1$  cm) GOV2 and IGV1 that were randomized to endoscopic obturation by cyanoacrylate (CYA) injection, NSBBs, and observation.<sup>53</sup> The number of patients with IGV1 was small (15%). Glue injection was associated with lower bleeding rates (10%) than NSBBs (38%) and observation (53%). Survival was better in the glue-treated group (93%) compared to observation (74%), but no different from NSBBs (83%). Although firm recommendations cannot be derived from this trial, the least invasive treatment is NSBBs and has the advantage that it may prevent other complications of cirrhosis.

#### Management of Gastric Variceal Bleeding

The current recommendations are to treat GOV1 (75% of all GV) as EV. By contrast, endoscopic therapy with tissue adhesives, mainly CYA,<sup>54</sup> is the recommended therapy for acute bleeding from GOV2 and IGV, including IGV1 (located in the fundus) and IGV2 (located anywhere in the stomach).<sup>55–59</sup> Lately, delivery of CYA under endoscopic ultrasound (EUS) guidance has been suggested to enable precise delivery of glue into the varix lumen and may improve the achieved obliteration rate and diminish adverse events.<sup>59–61</sup> Follow-up EUS may also be important to evaluate obliteration of larger varices and to retreat if necessary. Band ligation may be used in small GOV2 varices if obliteration

with tissue adhesives is not available. Balloon tamponade with the Linton-Nachlas tube may serve as a bridge to derivative treatments in massive bleedings.<sup>62</sup>

#### Prevention of Rebleeding From Gastric Varices

##### Endoscopic Variceal Obturation (CYA Glue Injection)

In one RCT, repeated CYA injection was superior to NSBBs preventing rebleeding and mortality in patients with cardiofundal varices.<sup>53</sup> In another trial, addition of NSBBs to CYA injection did not improve rebleeding or mortality compared to CYA injection alone.<sup>54</sup>

##### Transjugular Intrahepatic Portosystemic Shunt

An RCT including patients with GOV1 and GOV2 varices showed TIPS to be more effective than glue injection in preventing rebleeding,<sup>55</sup> with more than a 90% success rate for initial hemostasis and a very low rebleeding rate, although survival was similar.

##### Balloon Occluded Retrograde Transvenous Obliteration (BORTO)

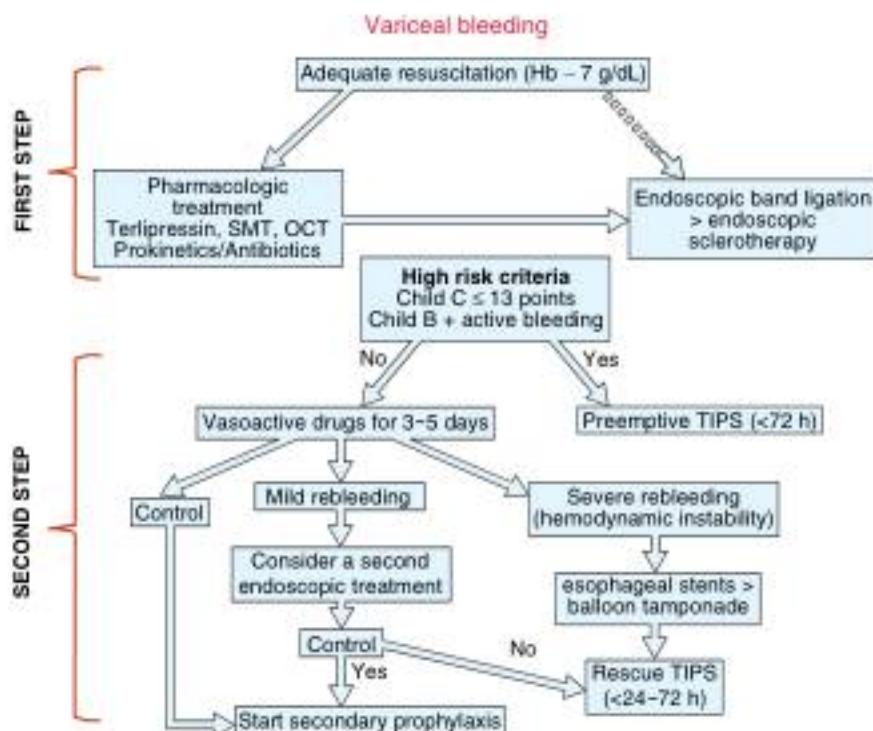

This procedure for treatment of fundal varices associated with a large gastro/splenorenal collateral involves retrograde catheterization of the left renal vein, followed by balloon occlusion and slow infusion of sclerosant to obliterate the gastro/splenorenal collateral and fundal varices.<sup>56–58</sup> BORTO could be an alternative treatment when TIPS cannot be performed, especially in patients with extrahepatic portal vein obstruction. BORTO presents the potential advantage over TIPS that it does not shunt portal blood flow away from the liver and therefore can be performed on patients with poor hepatic reserve.

#### PORTAL HYPERTENSIVE GASTROPATHY

Portal hypertensive gastropathy, and other gastric vascular lesions observed in patients with cirrhosis, is discussed in Chapter 18.

#### SUMMARY (FIG. 15.8)

Portal hypertensive bleeding is a dreaded complication of patients with cirrhosis and portal hypertension. Primary prophylaxis to avoid bleeding from varices should be done in patients with a high risk of bleeding (i.e., Child B or C cirrhosis or presence of red wale marks). Patients should receive therapy with nonselective  $\beta$ -blockers if there are no contraindications. Those patients who develop side effects or have contraindications to  $\beta$ -blockers should be offered endoscopic variceal band ligation. Initial management of acute variceal bleeding should focus on resuscitation with adequate volume replacement, careful blood transfusions of blood to keep hemoglobin levels at 7 g/L, antibiotic prophylaxis, and endotracheal intubation in selected cases. Standard of care mandates for early administration of vasoactive drugs and EBL within the first 12 hours of the index bleed. In addition, patients should be evaluated to decide if they are candidates for a preemptive TIPS. Patients that fail combined pharmacological and endoscopic therapy may require temporary placement of balloon tamponade or esophageal stents until definitive treatment (preferably TIPS) can be instituted. Given the available data, esophageal stents in this setting are preferred. Patients that fail the previously mentioned therapies should undergo an evaluation for TIPS. Patients that recover from an episode of variceal bleeding should undergo combination therapy with endoscopic

**FIG 15.8** Recommended algorithm for the treatment of an episode of acute variceal bleeding (AVB). Placement of transjugular intrahepatic portosystemic shunts (TIPS) (within 72 hrs) for patients AVB with Child B actively bleeding or C cirrhosis (< 13 points) is associated with a significant reduction in rebleeding and mortality and can be considered in such cases. Temporary measures include placement of an esophageal stent or balloon tamponade. Esophageal stents are preferred, as they are safer and more effective. The use of the balloon is associated with potentially lethal complications such as aspiration and perforation of the esophagus. Hb, haemoglobin; OCT, octreotide; SMT, somatostatin.

variceal ligation plus nonselective β-blockers for the prevention of recurrent VH. Bleeding episodes from gastric varices GOV2 + IGV1 are usually severe and sometimes difficult to control. Endoscopic injection of N-butyl-2-cyanoacrylate glue is one of the cornerstones of therapy as this measure is effective in over 90% to 95% of patients presenting with acute bleeding from gastric varices. Patients that cannot be controlled by this measure require TIPS.

## INTRODUCTION

Acute severe lower gastrointestinal (GI) bleeding is a common problem and frequent reason for hospitalization. Colonoscopy is often performed for diagnosis and potential therapeutic intervention. This chapter focuses on moderate to severe acute lower GI bleeding, defined as hematochezia, from a bleeding source distal to the ileocecal valve with an onset of less than 3 days of duration. This presentation usually prompts presentation to the emergency room and subsequent hospitalization.

## EPIDEMIOLOGY

Lower GI bleeding occurs at a rate of 36.5 per 100,000 in the adult population, based on a national inpatient database.<sup>1</sup> Assuming that an average, full-time clinical gastroenterologist is responsible for 50,000 adult lives, he or she would see approximately 20 cases per year. Most cases occur in elderly patients, given the increased frequency and risk for diverticulosis, vascular disease, and colonic malignancy.<sup>2</sup> Risk of lower GI bleeding is also associated with the use of aspirin and nonsteroidal antiinflammatory drugs (NSAIDs).<sup>3,4</sup>

A large US database study comprising 227,000 patients with discharge diagnoses of lower GI bleeds in 2002 reported an overall mortality rate of 3.9%.<sup>5</sup> A more recent (2012) study examining a national inpatient database revealed a lower mortality rate of 1.5% in 2009.<sup>1</sup>

## INITIAL APPROACH TO A PATIENT WITH HEMATOchezIA

The initial approach to a patient with lower GI bleeding is directed towards determining the severity of bleeding, the etiology, and

volume resuscitation. This includes obtaining a thorough history, orthostatic vital signs, laboratory testing, and physical and rectal examinations. Patients should be asked about whether they saw red blood or dark maroon blood, duration of symptoms, previous episodes of GI bleeding, a history of peptic ulcer disease, symptoms of abdominal pain or fever, travel history, prior colonoscopy or endoscopy results, prior pelvic radiation, surgical history, history of diverticulosis, and prior abdominal imaging studies. Patients should also be asked about use of medications associated with GI bleeding (e.g., aspirin, NSAIDs, and anticoagulants). Accompanying symptoms of weight loss or a change in bowel habits suggests possible colon cancer. Abdominal pain usually suggests ischemic colitis, although abdominal pain can be present in other colitides and malignancy. The presence of fever and leukocytosis is also suggestive of a colitis.

The most important parts of the physical examination are the vital signs and the stool/rectal examination. The presence of bright red blood on rectal examination strongly suggests the possibility of colonic bleeding. Bright red blood per rectum is generally from a colonic source, unless it is accompanied by hypotension, which can either occur during a severe upper GI bleed or a small bowel bleed with rapid transit of blood.<sup>6</sup> An elevated blood urea nitrogen/creatinine (BUN/Cr) ratio of greater than 30 is suggestive of an upper GI source of bleeding.<sup>7</sup> In the setting of hematochezia without hypotension, placement of a diagnostic nasogastric (NG) tube is usually unnecessary because it is unlikely that there is a severe upper GI bleed without hypotension. If there is hypotension and hematochezia, a severe upper GI bleed is possible, and an NG tube should be placed. A clear NG tube lavage does not always imply a lower GI source because 16% of patients with duodenal ulcer bleeds have negative NG lavage.<sup>8</sup> If bile is seen in the NG tube lavage, it is unlikely to be an upper GI bleed. Physical examination should also focus

**Abstract**

Acute severe lower gastrointestinal (GI) bleeding is a common problem and frequent reason for hospitalization with associated morbidity and mortality. Colonoscopy is often performed for diagnosis and potential therapeutic intervention. However, the optimal timing of colonoscopy remains unclear at this time. Common etiologies of lower GI bleeding include diverticulosis, postpolypectomy bleeding, arteriovenous malformation, colitis, malignancy, and radiation proctitis. Endoscopy therapy for lower GI bleeding is usually successful through a combination of hemoclips, injection of epinephrine, or ablation and coagulation. In cases of endoscopic failure, angiography and embolization are alternate therapeutic options. Surgery to control bleeding is rarely required.

colonoscopy

on abdominal tenderness, surgical scars, and stigmata of liver disease. At least one large bore intravenous catheter should be placed, with two placed in the setting of ongoing bleeding to allow for adequate resuscitation and transfusion as needed.

Blood should be sent for complete blood count, international normalized ratio (INR), chemistry panel, and type and crossmatch for packed red blood cells. Resuscitation should be initiated simultaneously with assessment. Intravenous fluids should be infused as fast as needed to keep systolic blood pressure greater than 100 mm Hg and pulse lower than 100 beats/min. Patients are transfused with packed red blood cells with a goal of 7 g/dL or a higher goal of 9 g/dL in the setting of massive bleeding or cardiac ischemia.<sup>9</sup>

Most patients with lower GI bleeding can be admitted to a medical ward. Patients with active bleeding should be admitted to a monitored intermediate care unit or intensive care unit (ICU), especially if there is persistent tachycardia or hypotension despite initial resuscitation. Hemoglobin levels should be obtained every 4 to 6 hours until the patient has a stable level. Patients older than age 60 or with risk factors for coronary artery disease should be evaluated for potential cardiac ischemia induced by anemia, hypotension, and blood loss.

Endoscopy of any sort should be done only when it can be performed safely and when the information may influence patient care. Patients should be resuscitated with fluids and transfusions before endoscopy. Ideally, patients should be hemodynamically stable, with a heart rate of less than 100 beats/min and systolic blood pressure greater than 100 mm Hg. Hemoglobin should be at least 7 g/dL. Severe thrombocytopenia (platelet count < 50,000/mm<sup>3</sup>) should be corrected with transfusions before emergency endoscopy, and elevated INR above 2.5 should be considered for correction with intravenous vitamin K or fresh frozen plasma. However, decisions to reverse anticoagulation should be made on an individual basis based on risk of thrombosis and severity of bleeding. Patients taking direct oral anticoagulants including rivaroxaban, apixaban, edoxaban, and dabigatran appear to have a similar risk of GI bleeding compared to patients taking warfarin.<sup>10-12</sup>

### **Early Predictors of Severity in Acute Lower Gastrointestinal Bleeding**

Early predictors (within 4 hours of admission) of severity for continued or recurrent bleeding after 24 hours of hospitalization include a heart rate greater than 100 beats/min, systolic blood pressure less than 115 mm Hg, syncope, nontender abdominal examination, observed rectal bleeding during the first 4 hours of hospital evaluation, aspirin ingestion, and the presence of more than two comorbid conditions (Box 16.1).<sup>13,14</sup> This prediction model has been prospectively validated; the low-risk group (no risk factors) had a 0% risk of rebleeding, the moderate-risk group (1–3 risk factors) had a 45% risk of rebleeding, and the high-risk group (> 3 risk factors) had a 77% risk of rebleeding.<sup>14</sup> It is possible that factors such as these can be used to help triage patients to the appropriate level of care, such as ICU, hospital ward, or outpatient evaluation, as well as urgent versus elective endoscopic evaluation.

Multivariate analysis found that independent predictors of in-hospital mortality were age (> 70 years), intestinal ischemia, presence of two or more comorbid illnesses, bleeding while hospitalized for a separate condition, coagulopathies, hypovolemia, transfusion of packed red blood cells, and male gender. Colorectal polyps and hemorrhoids were associated with a lower mortality

### **BOX 16.1 Early Predictors of Severity of Continued or Recurrent Lower Gastrointestinal**

#### **Bleeding**

- Heart rate >100 beats/min
- Systolic blood pressure < 115 mm Hg
- Syncope
- Nontender abdominal examination
- Observed rectal bleeding during first 4 hours of hospital evaluation
- Aspirin
- More than two comorbid conditions

From Strate LL, Orav EJ, Syngal S: Early predictors of severity in acute lower intestinal tract bleeding. *Arch Intern Med* 163:838–843, 2003; and Strate LL, Saltzman JR, Ockubo R, et al: Validation of a clinical prediction rule for severe acute lower intestinal bleeding. *Am J Gastroenterol* 100:1821–1827, 2005.

risk. Patients who develop severe lower GI bleeding while hospitalized for other lesions have a much higher mortality rate than patients admitted with lower GI bleeding. In a large retrospective study, the in-hospital mortality rate for patients with lower GI bleeding who began as outpatients was 2.4% compared with 23% for patients with in-hospital lower GI bleeding ( $P < .001$ ).<sup>15</sup>

### **DIAGNOSTIC OPTIONS**

Most patients should undergo initial evaluation with colonoscopy after adequate bowel preparation. However, in selected cases, flexible sigmoidoscopy with enema or oral bowel preparation can be considered. Other diagnostic tests such as angiography, computed tomography (CT) scans (including CT colonography and CT angiography), and tagged red blood cell nuclear scans, can be considered.

#### **Anoscopy**

Anoscopy can be useful if actively bleeding hemorrhoids are suspected. However, nearly every patient requires additional visualization of the more proximal colon using colonoscopy or possibly sigmoidoscopy. Therefore anoscopy is of limited utility in the setting of moderate to severe lower GI bleeding and is rarely performed for this purpose.

#### **Flexible Sigmoidoscopy**

Occasionally, flexible sigmoidoscopy may be performed to quickly evaluate the left side of the colon for any bleeding site stigmata, rather than waiting for a full colonoscopy bowel preparation, and this results in a diagnosis in approximately 9% of cases.<sup>15</sup> Flexible sigmoidoscopy can be considered in those with imaging studies such as CT scan or prior colonoscopy, suggesting a distal source of bleeding or postpolypectomy bleeding where the location of blood loss is strongly suspected to be distal. This may also be appropriate for patients with a suspected left-sided colitis or obstructing mass.

#### **Nuclear Medicine Scintigraphy**

Nuclear medicine scintigraphy involves injecting a radiolabeled substance in the patient's bloodstream and then performing serial scintigraphy to detect focal collections of radiolabeled material. It has been reported to detect bleeding at a rate of 0.1 mL/min.<sup>16</sup> The overall positive diagnostic rate is approximately 45%, with

a 78% accuracy in the localization of the true bleeding site.<sup>17</sup> The most common false-positive result occurs when there is rapid transit of luminal blood such that labeled blood is detected in the colon, although it originated in the upper GI tract. The main drawback to nuclear medicine scintigraphy is that it results in a delay to therapeutic intervention in those with active bleeding. Scintigraphy may be better suited for intermittent, obscure, overt GI bleeding despite evaluation with endoscopy and colonoscopy.<sup>1</sup>

### Angiography

In patients with severe hematochezia from a lower GI source felt to be too unstable for colonoscopy, angiography with the intention of embolization should be considered. NG tube placement or upper endoscopy (EGD) should be considered first to rule out a brisk upper GI bleed. Angiography is positive when the arterial bleeding rate is at least 0.5 mL/min.<sup>18</sup> The diagnostic yield depends on patient selection, timing of the procedure, and the skill of the angiographer, with positive yields in 12% to 69% of cases. Advantages of angiography are the ability to perform the procedure immediately without the need for bowel preparation, the opportunity for therapeutic embolization at the same time, and the ability to manage upper GI or small bowel bleeds that were incorrectly presumed to be a lower GI bleed. Disadvantages include a 3% rate of major complications, including hematoma formation, femoral artery thrombosis, contrast dye reactions, renal failure, and transient ischemic attacks.<sup>19</sup> Another disadvantage is the requirement for active bleeding at the time of angiography, otherwise a target is not visible for embolization.

### Computed Tomography

Urgent contrast enhanced multidetector CT has been studied in the evaluation of lower GI bleeding. A large retrospective series of 1604 patients with a lower GI bleed who underwent urgent CT scan performed within the first 24 hours reported higher rates of bleeding source identification during colonoscopy (68% vs. 20%) in diverticular bleeding when contrast extravasation was detected on CT scan.<sup>20</sup> The same study also suggested that CT scan also helps determine optimal timing of colonoscopy as elective colonoscopy can be done in patients with colonic thickening on CT, suggesting colitis or malignancy, and urgent colonoscopy should be done in the absence of these findings. CT scan should be considered early in the course of evaluation in patients with significant abdominal pain, fevers, leukocytosis, and risk factors for vascular disease to evaluate for colitis, which may preclude the need for urgent colonoscopy in patients with self-limited lower GI bleeding. Colonoscopy can be performed on an elective basis in these patients, especially at centers where colonoscopy is not readily available.

### Colonoscopy

Urgent colonoscopy using a rapid purge has been shown to be safe, to provide important diagnostic information, and sometimes to allow therapeutic intervention.<sup>21</sup> Patients usually ingest 4 to 8 L of polyethylene glycol either orally or via NG tube over 3 to 5 hours until the rectal effluent is clear of stool, blood, and clots. Metoclopramide may be given intravenously before the purge and repeated after 3 to 4 hours to facilitate gastric emptying and reduce nausea.

Most "urgent" colonoscopies for lower GI bleeds are performed 6 to 36 hours after the patient is admitted to the hospital. Because

most bleeding stops spontaneously, cases are often performed electively the day after hospitalization to allow the patient to receive blood transfusions and to finish the bowel preparation.

The overall diagnostic yield of a presumed or definite etiology using colonoscopy in lower GI bleeding ranges from 48% to 90%, with an average of 68%, based on a review of 13 studies.<sup>17</sup> The problem with interpreting these data is that it is often impossible to determine a definite diagnosis of the cause of the bleeding, unless bleeding stigmata are identified, such as active bleeding, a visible vessel, an adherent clot, mucosal friability or ulceration, or the presence of fresh blood limited to a specific part of the colon. A presumptive diagnosis is often made, especially in the case of diverticular bleeding, in which no blood is seen but there is a potential bleeding site present.

The optimal time for performing urgent bowel preparation and colonoscopy is unknown. Theoretically, the sooner the colonoscopy is performed, the higher the likelihood of finding a lesion that might be amenable to hemostasis, such as a bleeding diverticulum or polyp stalk. However, a retrospective study from the Mayo Clinic suggested that there was no significant association between the time of endoscopy (0 to 12 hours, 12 to 24 hours, > 24 hours) and the findings of active bleeding or other stigmata that would prompt colonoscopic hemostasis in patients with diverticular bleeding.<sup>22</sup> A randomized trial comparing urgent colonoscopy within 12 hours to colonoscopy performed within 36 to 60 hours reported similar outcomes with regards to further bleeding, blood transfusions, hospital days, subsequent therapeutic interventions for bleeding, and hospital charges.<sup>1</sup> Therefore, the benefit of urgent over elective colonoscopy has not been clearly established.

### Surgery

Surgical management is rarely needed for lower GI bleeding because most bleeding is either self-limited or managed with endoscopic therapy or angiography. The main indications for surgery are malignant lesions and recurrent bleeding from diverticula.

## Etiology and Pathogenesis of Severe Lower Gastrointestinal Bleeding

It is not always possible to visualize active bleeding during colonoscopy. A definite diagnosis of a bleeding lesion can usually be made if active bleeding is seen or if there are obvious stigmata, such as an adherent clot or visible vessel. A presumptive diagnosis can be made if there is a suspicious lesion and no other possible sources. Table 16.1 lists the frequency of various presumed or definite sites of acute colonic bleeding.<sup>23</sup> Potential colonic lesions amenable to endoscopic hemostasis include diverticula, post-polypectomy bleeding, angiodysplasia, hemorrhoids, Dieulafoy's lesions, tumors, ulcers, varices, and radiation proctitis.

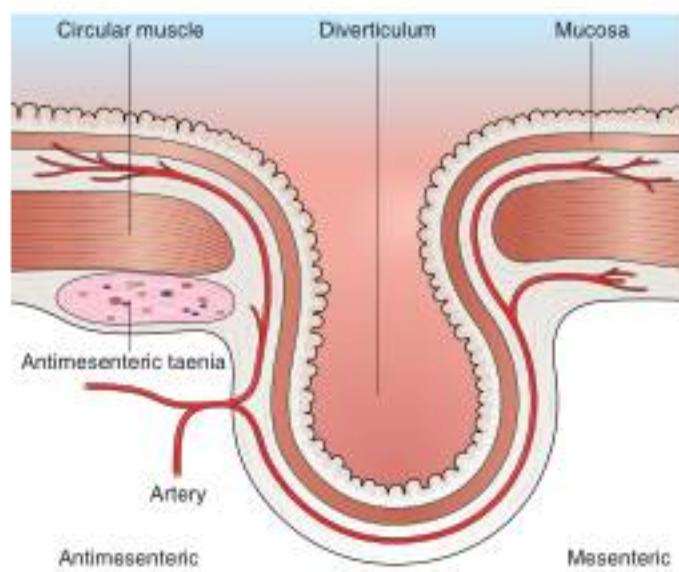

### Diverticular Bleeding

Colonic diverticula are herniations of colonic mucosa and submucosa through the muscular layers of the colon. Diverticula in the colon are actually pathologic pseudodiverticula because true diverticula contain all layers of the intestinal wall. Colonic diverticula seem to form when colonic tissue is pushed out by intraluminal pressure. Diverticula occur at the point of entry of the small arteries that supply the colon, the vasa recta, as they penetrate the circular muscle layer of the colonic wall (Fig. 16.1). The entry points of the vasa recta are areas of relative weakness

**FIG 16.1** Vascular anatomy of colonic diverticulum.

through which the mucosa and submucosa can herniate when under increased intraluminal pressure. They vary in diameter from a few milliliters to several centimeters. The most common location is the left colon.

Most colonic diverticula are asymptomatic and remain uncomplicated. Bleeding may occur from vessels at the neck or base of the diverticulum.<sup>24</sup> Diverticula are common in Western countries, with a prevalence of 50% in older adults.<sup>25</sup> In contrast, less than 1% of people living in continental Africa and Asia have diverticula.<sup>26</sup> This finding has led to the hypothesis that regional differences in prevalence can be explained by the low amounts of dietary fiber in Western diets. Presumably, a low-fiber diet results in less stool content, longer fecal transit time, increased colonic muscle contraction, and, ultimately, increased intraluminal pressure that results in the formation of pulsion diverticula. In addition, diverticula occur with increasing frequency with advanced age, which could be a result of weakening of the colonic wall and muscle tone.

It has been estimated that 3% to 5% of patients with diverticulosis develop diverticular bleeding.<sup>27</sup> Although most diverticula are in the left colon, several series suggest that bleeding diverticula

**FIG 16.2** Stigmata of recent bleeding from a diverticulum.

occur more often in the right colon.<sup>24,27-29</sup> Patients with diverticular bleeding are typically elderly and present with painless hematochezia. They have often been taking aspirin or NSAIDs. In at least 75% of patients with diverticular bleeding, the bleeding stops spontaneously.<sup>29</sup> Patients in whom bleeding stops usually require less than 4 units of blood transfusion. Patients with successful resection of a bleeding diverticulum had a rebleeding rate of 4%.<sup>29</sup> Among patients in whom bleeding stopped spontaneously, the rebleeding rate from colonic diverticulosis was 25% to 38% over the next 4 years.<sup>24,28</sup> Urgent colonoscopy after rapid bowel preparation often reveals that bleeding has stopped by the time of colonoscopy, and only nonbleeding diverticula are detected. These patients are given the diagnosis of "presumptive diverticular bleed" because the diverticula are the only likely source of bleeding, although no stigmata were identified.

Occasionally, urgent colonoscopy reveals stigmata of recent bleeding, such as active bleeding, a visible vessel, clot, or blood limited to one segment of the colon (Fig. 16.2). It seems possible that earlier colonoscopy in lower GI bleeding would result in a greater frequency of finding stigmata of recent diverticular bleeding. However, a small case series did not find any differences in the detection rate of active bleeding or bleeding stigmata if colonoscopy was performed between 0 and 12 hours, 12 and 24 hours, or more than 24 hours from the time of hospital admission.<sup>30</sup> There have been attempts to stratify patients with diverticular bleeding at increased risk for rebleeding, employing the same endoscopic stigmata used in high-risk peptic ulcer bleeding (active bleeding, visible vessel, and clot), although the natural history for each of these untreated stigmata is unknown. The "pigmented protuberance" found on the edge of some diverticula at histopathology is usually clot at the edge of a ruptured blood vessel.<sup>31</sup>

The UCLA/CURE group found that among patients with stigmata of recent diverticular hemorrhage (six active bleeding, four visible vessels, and seven adherent clots), there was a very high rebleed rate of 53% and an emergency surgery rate of 35%.<sup>31</sup> Colonoscopic hemostasis of actively bleeding diverticula has been reported using bipolar probe coagulation, epinephrine injection,

metallic clips, rubber band ligation, and fibrin glue.<sup>33–37</sup> If fresh red blood is seen in a focal segment of colon, we try to examine this segment of bowel carefully to detect the exact bleeding site. If the bleeding is coming from the edge of the diverticulum or there is a pigmented protuberance on the edge, we initially inject 1:10,000 epinephrine in 1-mL aliquots using a sclerotherapy needle into four quadrants around the bleeding site. Then we use either an endoscopic clip or a bipolar probe at a low power setting (10 to 15 W) and light pressure for a 1-second pulse duration to cauterize the diverticular edge and stop bleeding or flatten the visible vessel. If there is a nonbleeding adherent clot, we inject around the clot with 1:10,000 epinephrine in four quadrants with 1 mL per quadrant and remove the clot in piecemeal fashion using a cold snare. The clot is shaved down until it is 3 mm above the diverticulum, and then the underlying stigma is treated with either endoscopic clip or bipolar probe coagulation as discussed previously. After performing endoscopic hemostasis of a bleeding diverticulum, a permanent submucosal tattoo and a metal clip (if not previously placed) should be placed in the adjacent mucosa to identify the site in case colonoscopy, angiographic embolization, or surgery is required for recurrent bleeding. For long-term management after colonoscopic hemostasis, patients are told to avoid NSAIDs.

In 2000, Jensen and colleagues in the UCLA/CURE group<sup>31</sup> published their results on urgent colonoscopy for diagnosis and treatment of severe diverticular hemorrhage. The investigators found that 20% of patients with severe hematochezia had endoscopic stigmata suggesting a definite diverticular bleed. Compared with a historical control group with high-risk stigmata but no colonoscopic hemostasis, the group receiving colonoscopic hemostasis had a rebleed rate of 0% versus 53% and an emergency hemicolectomy rate of 0% versus 35%. After 3 years of follow-up, there were no rebleeding episodes in the patients who underwent colonoscopic hemostasis. In contrast to the UCLA experience, a smaller, retrospective review of the Duke University reported 13 patients with active bleeding or stigmata who received endoscopic treatment with epinephrine or bipolar coagulation or both.<sup>38</sup> The 30-day rebleed rate was 38%; four of these patients underwent surgery. The long-term rebleed rate was 23% with a mean follow-up of 3 years.

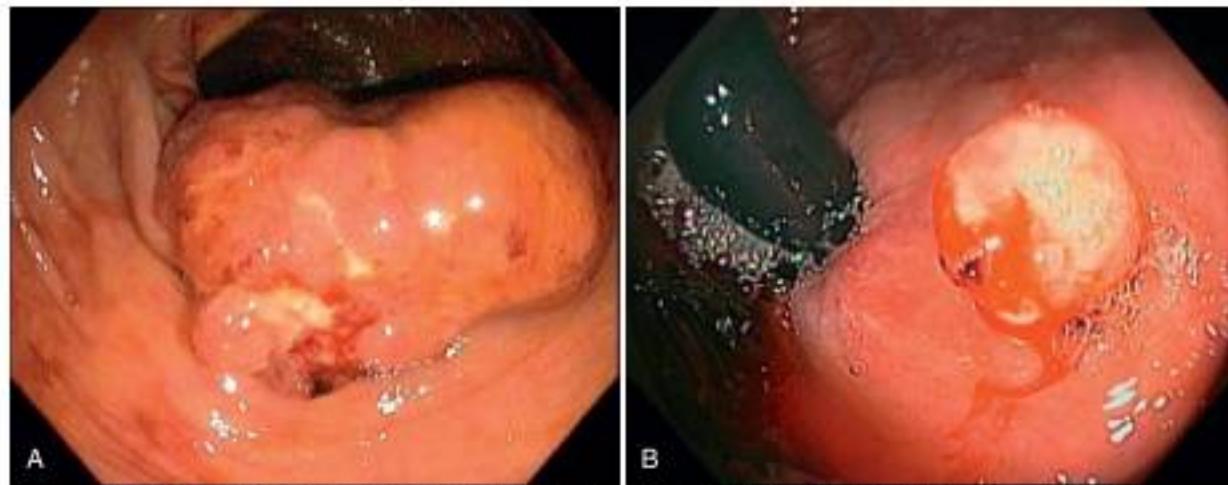

Angiographic embolization can also be performed in selected cases of diverticular bleeding, but there is a risk of bowel infarction and renal failure. Surgical resection for diverticular bleeding is usually reserved for recurrent bleeding episodes. Resection should be guided by colonoscopic, angiographic, or nuclear medicine studies showing the likely bleeding site. The need for surgery is often guided by certainty regarding the bleeding site and medical comorbidity because diverticular bleeding is often mild, and the risks of surgical complications are increased in elderly patients.

### Colon Cancer

Most patients with colon cancer present with occult GI blood loss rather than hematochezia. For adult patients with hematochezia, determining the presence or absence of a colon cancer is imperative because early diagnosis improves survival. Because a cancer must ulcerate for overt bleeding to occur, most bleeding cancers are at a relatively advanced tumor stage (Fig. 16.3A) but can be seen with nonmalignant polyps (see Fig. 16.3B). Bleeding is usually mild and self-limited. Active bleeding from a malignant colonic lesion is often challenging given the large size of lesions, abnormal nature of the tissue, and often diffuse nature. For instances of bleeding from a focal area of a malignant lesion, endoscopic clipping either with traditional or over the scope clips, bipolar cauterization, or epinephrine injection can be considered. There are reports of successful hemostasis on bleeding colonic malignancies with hemostatic powders that have the benefit of ease of use and ability to treat larger areas.<sup>39</sup>

### Colitis

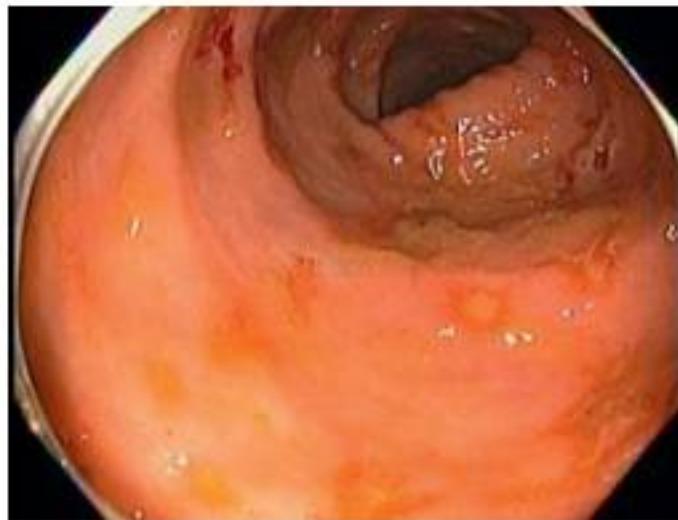

The term *colitis* refers to any form of inflammation of the colon. With regard to severe lower GI bleeding, this is usually ischemic colitis, inflammatory bowel disease, or possibly infectious colitis. Ischemic colitis generally manifests as hematochezia with left-sided abdominal discomfort. It results from mucosal hypoxia and is thought to be caused by hypoperfusion of the intramural vessels of the intestinal wall rather than by large vessel occlusion. Most cases do not have a recognizable cause, but associated conditions include recent aortic or cardiac surgery, vasculitis, and medications.<sup>40,41</sup> Because of collateral circulation, ischemic involvement is usually segmental and primarily affects the mucosal aspect of

**FIG 16.3** **A**, Colon cancer as source of hematochezia. **B**, Nonmalignant polyp as source of hematochezia.

**FIG 16.4** Ischemic colitis.

**FIG 16.6** Infectious colitis with ulceration.

**FIG 16.5** Crohn's colitis with ulceration.

the intestine. The colon is mostly affected in the watershed areas, such as the splenic flexure or rectosigmoid junction in which there is reduced collateral circulation, although ischemia can occur anywhere.

The diagnosis of ischemic colitis is usually confirmed by colonoscopy but can be suspected by "thumbprinting" on plain film radiographs or, more commonly, colonic wall thickening on CT scan. The colonoscopic appearance includes erythema, friability, and exudate (Fig. 16.4). Biopsy specimens may be suggestive of ischemic changes but, more importantly, are used to exclude Crohn's disease and infection. Ischemic colitis generally resolves in a few days and does not require colonoscopic hemostasis. In a large retrospective series from Kaiser Permanente San Diego, there were no episodes of rebleeding from ischemic colitis over a 4-year period.<sup>1</sup> Inflammatory bowel disease affecting the colon can cause friability and ulceration of the colon (Fig. 16.5) though rarely cause severe acute lower GI bleeding. In a case series from the Mayo Clinic, most patients had Crohn's disease<sup>12</sup> and were successfully treated medically. Three of the 31 patients in the

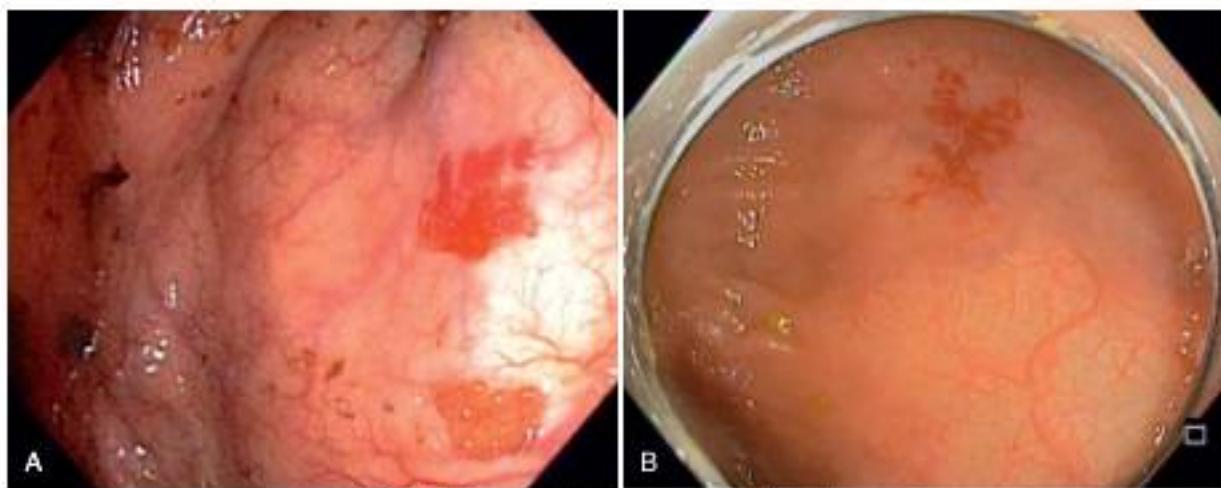

series received endoscopic therapy with epinephrine injection alone or with bipolar coagulation for adherent clots or oozing ulcers in Crohn's disease. Of the patients with Crohn's disease with severe bleeding, 39% required surgical management.

Infectious colitis should be excluded in any patient with severe lower GI bleeding and colitis. Lower GI bleeding can occur with infection by *Campylobacter jejuni*, *Salmonella*, *Shigella*, invasive *Escherichia coli*, *E. coli* 0157, *Clostridium difficile*, or *cytomegalovirus*. Significant blood loss is rare. Diagnosis is made by stool testing and flexible sigmoidoscopy which can reveal a nonspecific colitis or ulcers (Fig. 16.6).

### Angiodysplasia

Colonic angiomas are also referred to as angiodysplasia, arteriovenous malformations, or vascular ectasias. These appear as flat or slightly raised, red, ectatic vessels that have been described to have a spider-like appearance (Fig. 16.7A, B). They are generally uncommon; less than 1% of asymptomatic patients undergoing screening colonoscopy were found to have angiodysplasia.<sup>13</sup> The lesions seem to increase with age and may represent degeneration of previously normal blood vessels in the cecum and proximal ascending colon. Histopathology reveals a large, dilated, submucosal vein and, in advanced cases, dilated mucosal veins with small arteriovenous communications. Proposed explanations for angioma formation include the partial obstruction of submucosal veins passing through the colonic muscle layers, with eventual dilation of the submucosal and mucosal veins, and local mucosal ischemia.

Medical conditions associated with angiomas include chronic renal failure and hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome). There have been reports suggesting that aortic stenosis is associated with lower GI bleeding, presumably from colonic angiomas.<sup>14</sup> The potential biologic explanation is that aortic stenosis causes defects in von Willebrand factor, which causes the patient to have decreased platelet adhesion and increased bleeding tendency, especially if there were preexisting mucosal GI lesions such as angiomas.<sup>15,16</sup> Clinical studies do not support the association between aortic stenosis and the presence of angiomas, however.<sup>17,18</sup> Bleeding from angiodysplasia is usually painless and usually occurs from the right colon.

**FIG 16.7 A and B.** Arteriovenous malformations.

In recent decades, it seems that the reported frequency of angiomas as the source of lower GI bleeding has decreased.<sup>21,22</sup> This may be because of better recognition of angiomas with improved endoscope technology and increased attribution to presumed diverticular bleeding as the cause of hematochezia. Endoscopic hemostasis with argon plasma coagulation is reported to be successful in 85% of cases though endoscopic clipping can be considered in patients on antiplatelet agents or anticoagulation (Video 16.1). In patients with persistent bleeding from angiodysplasia, treatment with thalidomide or octreotide can lead to a clinical response in 71% and 77% of patients, respectively.<sup>49</sup>

### Postpolypectomy Bleeding

Postpolypectomy bleeding occurs after between 1% and 6% of polypectomies, usually within the first 7 days.<sup>50</sup> It is generally mild and self-limited. Reported risk factors for postpolypectomy bleeding include large polyps (> 2 cm), thick stalks, sessile polyps, and right colon polyps.<sup>51</sup> The endoscopic appearance of delayed postpolypectomy bleeding can be variable depending on the timing of colonoscopy. The appearance can range from a well-defined, clean-based ulceration (Fig. 16.8A, B) to active bleeding from a poorly defined ulcerated region (see Fig. 16.8C). Endoscopic management techniques include hemoclips, epinephrine injection, thermal coagulation, and endoloops (Fig. 16.9, Videos 16.2 and 16.3).<sup>52–55</sup> In a case series from the Mayo Clinic, the median time to bleeding after polypectomy was 5 days (range 0 to 17 days).<sup>52</sup> Of patients, 65% received aspirin, NSAIDs, warfarin, heparin, or steroids after polypectomy; 76% required transfusions; and 96% were managed endoscopically with coagulation or epinephrine injection or both. A randomized trial of 413 patients demonstrated no reduction in the risk of postpolypectomy with routine clipping in polyps with a mean size of 8 mm.<sup>54</sup> A 2013 series on polypectomy of sessile or flat polyps greater than 2 cm in size demonstrated a significant reduction in postpolypectomy bleeding from 10% to 2% when the defect is completely closed.<sup>51</sup>

### Radiation Proctitis

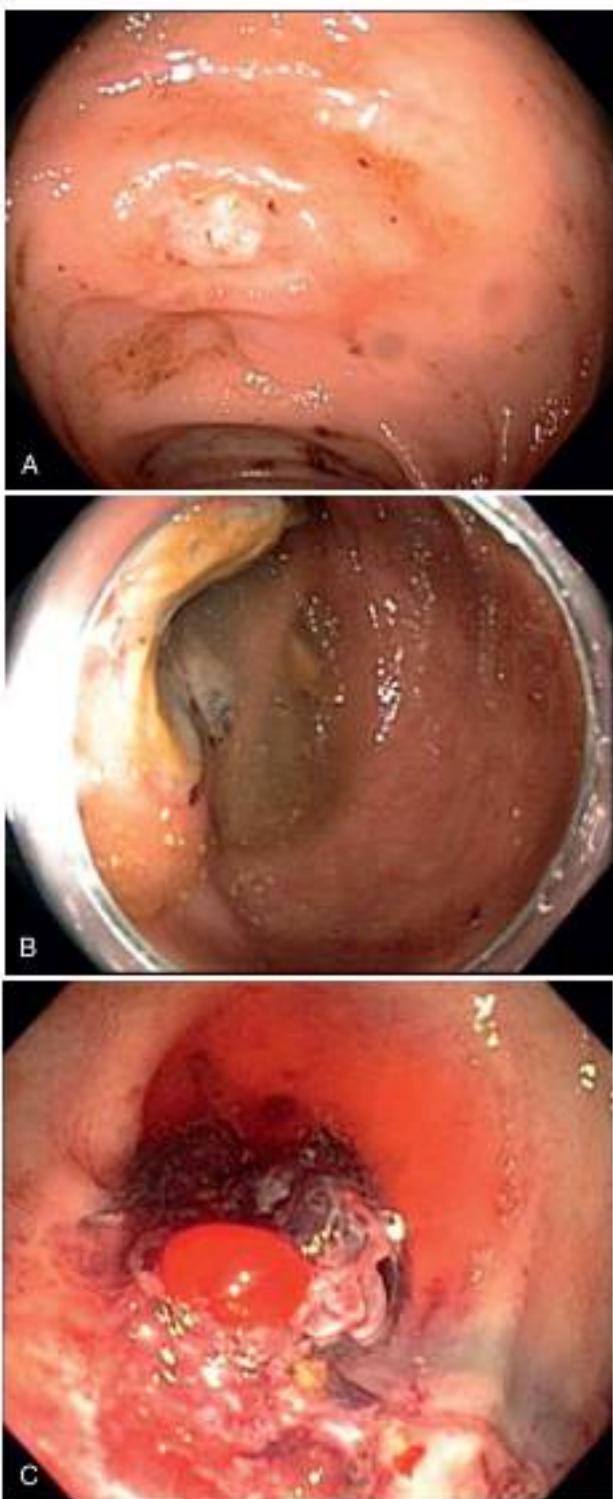

Radiation proctitis usually causes mild, chronic hematochezia but occasionally can cause acute severe lower GI bleeding. Ionizing radiation can cause acute and chronic damage to the normal

colon and rectum after radiation treatment for gynecologic, prostatic, bladder, or rectal tumors. Approximately 75% of patients who receive 4000 rad develop acute, self-limited diarrhea, tenesmus, abdominal cramping, and, rarely, bleeding during the first few weeks. Chronic radiation effects occur 6 to 18 months after completion of treatment. Bowel injury resulting from chronic radiation is related to vascular damage, with subsequent mucosal ischemia, thickening, and ulceration. Much of this damage is believed to be due to chronic hypoxic ischemia and oxidative stress. Flexible sigmoidoscopy reveals telangiectasia, friability, and ulceration in the rectum (Fig. 16.10).

Patients should be instructed to avoid all aspirin and NSAIDs and should be put on a high-fiber diet. Medical therapies with topical or oral 5-aminosalicylic acid, sucralfate, or formalin can be tried with variable success.<sup>56–58</sup> Thermal therapy with argon plasma coagulation (APC), bipolar probe coagulation, radiofrequency ablation, and cryotherapy can be quite successful.<sup>57–59</sup> However, thermal therapy has the potential to result in ulceration which can result in further bleeding, especially in those on antiplatelet agents or anticoagulants (Fig. 16.11). Patients with refractory radiation proctitis may experience improvement with hyperbaric oxygen therapy.<sup>60</sup>

### Hemorrhoids

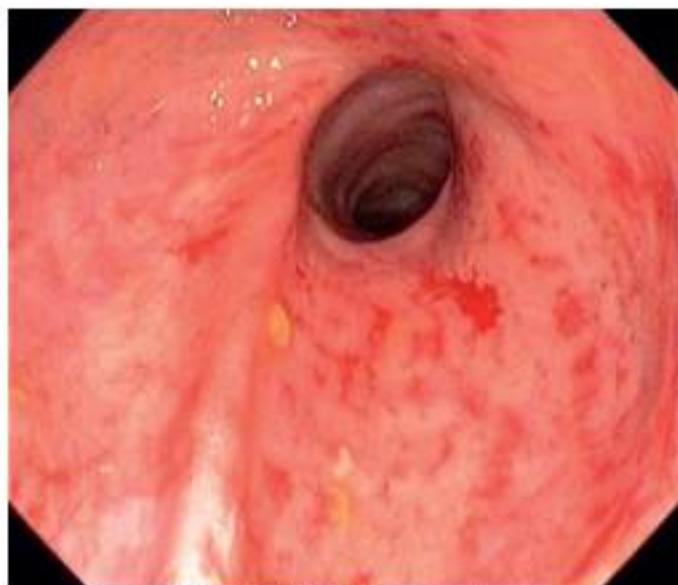

Hemorrhoids are a plexus of veins just above the rectal squamocolumnar junction. Internal hemorrhoids are located above the dentate line, and external hemorrhoids are located below the dentate line. Symptomatic hemorrhoids are common in adults, mostly associated with prolonged straining during bowel movements, chronic constipation, pregnancy, obesity, and low-fiber diet. Bleeding is characterized by bright red blood per rectum that can coat the outside of the stool, may drip into the toilet bowel, and is present when wiping with tissue. Usually this is mild bleeding, but occasionally severe bleeding may occur from hemorrhoids. Treatment of hemorrhoids usually starts with medical therapy consisting of fiber supplementation to soften stool, lubricant rectal suppositories (with or without steroids), and warm sitz baths. Anoscopic therapy can also be used, including rubber band ligation, injection sclerotherapy, cryosurgery, infrared photocoagulation, and bipolar and direct current electrocoagulation. The use of a flexible endoscope and band ligation devices have also been described.<sup>62</sup> A disposable bander has been shown

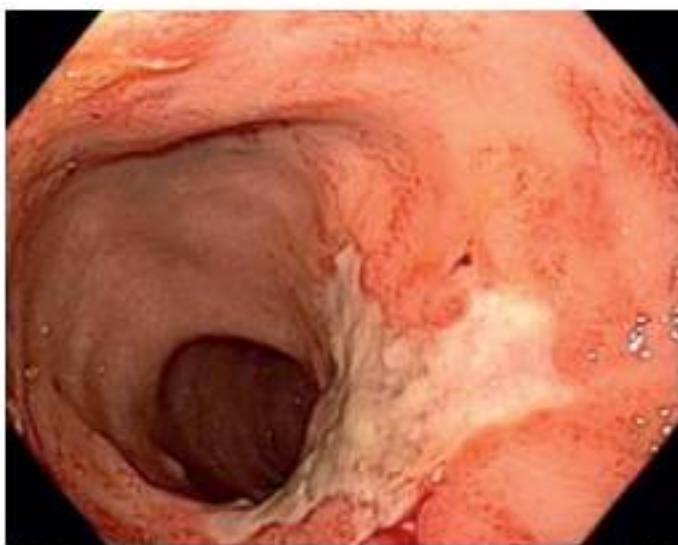

**FIG 16.8** **A**, Clean based ulcer from postpolypectomy site. **B**, Large ulceration from postpolypectomy site. **C**, Active bleeding from postpolypectomy site.

**FIG 16.9** Hemoclip placement over postpolypectomy ulcer.

**FIG 16.11** Ulceration after argon plasma coagulation (APC) treatment of radiation proctitis.

**FIG 16.12** Rectal varices.

**FIG 16.13** Active bleeding from a rectal Dieulafoy's lesion.

to be a technically simple method of hemorrhoid treatment with good results with a low rate of complications.<sup>53</sup> Surgery is reserved for refractory bleeding not controlled with other mechanisms. Most patients respond to medical management.

### Rectal Varices

In response to portal hypertension, varices can develop in the rectal mucosa between the superior hemorrhoidal veins (portal circulation) and the middle and inferior hemorrhoidal veins (systemic circulation). On endoscopic examination, rectal varices are seen as vascular structures located several centimeters above the dentate line (Fig. 16.12). The incidence of rectal varices increases with the degree of portal hypertension. Approximately 60% of patients with a history of bleeding esophageal varices have rectal varices. Rectal varices can be treated similarly to esophageal varices, with sclerotherapy, rubber band ligation, or portosystemic shunts.<sup>54,55</sup> Endoscopic ultrasound-guided coil and/or glue treatment of rectal varices can be considered in refractory cases or where visualization is impaired due to brisk bleeding.<sup>56</sup>

### Dieulafoy's Lesion

Dieulafoy's lesions are large submucosal arteries without overlying mucosal ulceration, which can cause massive bleeding from the colon and rectum (Fig. 16.13). There have been reports of bleeding Dieulafoy's lesions in the rectum that were treated successfully with endoscopic hemostasis, including cauterization and hemoclip placement.<sup>57,58</sup>

### SUMMARY

The source of severe lower GI bleeding can usually be diagnosed by urgent colonoscopy. The differential diagnosis of lower GI bleeding includes diverticulosis, cancer, colitis, angiomas, post-polypectomy sites, radiation proctitis, internal hemorrhoids, and rectal varices. Patients should be stabilized with medical resuscitation and transfusion before urgent colonoscopy. Urgent colonic purge allows for earlier colonoscopy and the increased possibility for colonoscopic hemostasis. Bleeding diverticula and postpol-

ypectomy bleeding can be treated with epinephrine injection, bipolar coagulation, or clipping. Radiation proctitis and angiomas can be treated with thermal coagulation. Most patients who have successful colonoscopic hemostasis do not experience rebleeding. After endoscopic hemostasis, medical management can often help reduce the chances of rebleeding. Urgent colonoscopy should be performed in all patients with severe hematochezia who are suspected of having a lower GI bleed.

## INTRODUCTION

Traditionally, obscure gastrointestinal bleeding (OGIB) is reported to account for approximately 5% of all gastrointestinal (GI) bleeding and is defined as bleeding from an unknown source that persists or recurs after negative bidirectional endoscopic diagnostic evaluations.<sup>1,2</sup> A negative bidirectional endoscopic diagnostic evaluation is defined as a negative upper endoscopy (esophagogastroduodenoscopy [EGD]) and negative colonoscopy with careful evaluation of the terminal ileum.<sup>1,2</sup> However, with the introduction of video capsule endoscopy (VCE) in 2001 and device-assisted deep enteroscopy in 2004 (e.g., double-balloon enteroscopy), and the ability to endoscopically visualize the entire length of the small bowel, the majority of patients who were previously classified as having "OGIB" were found to have a small bowel source of bleeding. Small bowel bleeding is now referred to as *middle GI bleeding* if the source of bleeding is located between the ligament of Treitz and the ileocecal valve. Thus today, following negative upper and lower endoscopic examinations and before performance of VCE, patients should be classified as having "suspected middle GI bleeding" with the diagnosis of true OGIB reserved only for patients who have also undergone a negative VCE examination.<sup>1,2</sup>

Overt *middle GI bleeding* refers to patients presenting with either melena or hematochezia with a source of bleeding identified in the small bowel. Furthermore, the term *occult middle GI bleeding* can be reserved for patients presenting with iron-deficiency anemia, with or without guaiac-positive stools, who are found to have a small bowel source of bleeding.<sup>1,2</sup>

## INVESTIGATING SUSPECTED MIDDLE GASTROINTESTINAL BLEEDING

### Push Enteroscopy

Push enteroscopy permits evaluation of the proximal small intestine to a distance that is approximately 50 to 100 cm beyond the ligament of Treitz. Dedicated video-enteroscopes (250 cm in length) are commercially available, but if these instruments are not available at the endoscopy site, a pediatric or standard adult colonoscope can be used with distance of insertion 40 to 50 cm beyond the ligament of Treitz. The use of an overtube, back-loaded onto the endoscope insertion tube, may help limit looping of the enteroscope within the stomach and facilitate deeper small bowel intubation.<sup>3</sup> Although the use of an overtube may allow for deeper small bowel intubation, it does not appear to increase the diagnostic yield of the test.<sup>4</sup> The diagnostic yield of push enteroscopy is reported to range from 3% to 70%, with most small bowel findings being vascular lesions (e.g., arteriovenous malformations). Interestingly, most of the lesions diagnosed during push enteroscopy have been found in locations accessible to standard EGD.<sup>3</sup>

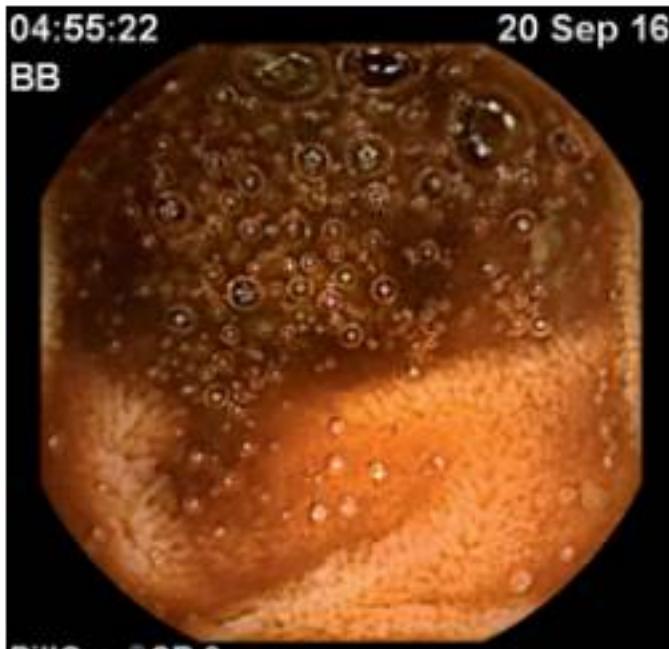

With the development of endoscopic tools/devices for dedicated video-enteroscopes, such as biopsy forceps, snares, thermal probes (contact and noncontact), and injection needles, push enteroscopy is preferred over radiologic diagnostic modalities because of the ability to obtain tissue, perform polypectomy or hemostasis if necessary, and mark lesion sites with an India ink tattoo or an endoscopic clip. However, push enteroscopy does not allow for the visualization of the entire small bowel, and

**Abstract**

Obscure gastrointestinal (GI) bleeding accounts for approximately 5% of all GI bleeding and has been defined as bleeding from an unknown source that persists or recurs after negative bidirectional endoscopic diagnostic evaluations (e.g., negative esophagogastroduodenoscopy and ileocolonoscopy). With the introduction of video capsule endoscopy and device-assisted deep enteroscopy, as well as the newfound ability to endoscopically visualize the entire length of the small bowel, the majority of patients who were previously classified as having obscure GI bleeding were actually found to have a small bowel source of bleeding. Thus, small bowel bleeding is now referred to as *middle GI bleeding* if the source of bleeding is located between the ligament of Treitz and the ileocecal valve. Thus today, following negative upper and lower endoscopic examinations and before performance of video capsule endoscopy, patients should be classified as having "suspected middle GI bleeding" with the diagnosis of true obscure GI bleeding reserved only for patients who have also undergone a negative endoscopic evaluation of the entire small bowel. This chapter will review the possible causes of middle GI bleeding and what diagnostic investigations are available including endoscopy, small bowel contrast radiography, cross-sectional imaging, nuclear medicine studies, and angiography. We also propose an evidence-based diagnostic strategy for the evaluation of middle GI bleeding and provide numerous demonstrative endoscopic images and video clips.

adverse events, including perforation and mucosal laceration, have been reported with the use of an overtube. With the advent of small bowel VCE and device-assisted "deep" enteroscopy, diagnostic push enteroscopy is less commonly used today.

### Video Capsule Endoscopy

VCE is an endoscopic technology that is readily available worldwide and capable of obtaining endoscopic images from the entire small bowel.<sup>1,2</sup> VCE is easy, minimally invasive, safe, patient-friendly, and is the first-line diagnostic tool in imaging the small bowel for pathologies. With this realization, there has been rapid uptake and wide acceptance of this endoscopic technology for detecting small bowel abnormalities.

VCE allows complete evaluation of the small bowel (from the duodenum to the ileocecal valve) in 79% to 90% of patients, with a reported diagnostic yield of 38% to 83% in patients with suspected small bowel bleeding (Figs. 17.1 and 17.2; Video 17.1).<sup>1,2</sup> The main utility of VCE lies in its high positive (94%–97%) and negative (83%–100%) predictive values in the evaluation of GI bleeding.<sup>3–12</sup> Findings at VCE leading to endoscopic or surgical intervention or a change in medical management have been reported in 37% to 87% of patients (Figs. 17.3 to 17.10; Videos 17.2 to 17.10).<sup>13</sup> In addition, 50% to 66% of patients have been reported to remain transfusion free without recurrent bleeding at follow-up after VCE-directed interventions.<sup>14</sup> In patients who have had a negative VCE study, rebleeding occurs in 6% to 27%.<sup>15,16</sup>

The diagnostic yield of VCE may be influenced by multiple factors, with a higher likelihood of positive findings in patients with a hemoglobin less than 10 g/dL, longer duration of bleeding (> 6 months), more than one episode of bleeding, overt as compared with occult bleeding (60% vs. 46%), and performance of VCE within 14 days of a bleeding episode (91% vs. 34%).<sup>17–19</sup> It has also been shown that detecting a source of bleeding depends on the timing of VCE investigation. In a study by Pennazio et al (2004), evaluating 100 consecutive patients undergoing VCE,

**FIG 17.3** Suspected celiac disease seen at video capsule endoscopy (VCE).

the diagnostic yield of VCE was 92% for patients with overt bleeding, 44% for occult bleeders, 67% for patients with prior overt bleeding who were studied within 10 to 14 days of their bleeding episode, and only 33% for those studied by VCE at 3 to 4 weeks after the bleeding episode.<sup>20</sup>

Limitations of VCE include lack of biopsy or therapeutic capabilities, inability to perform endoscopic marking, inability

to control movement of the capsule through the GI tract, and difficulty in localizing lesions. Other limitations of VCE include a lack of specificity, with 14% incidental findings in healthy volunteers<sup>21</sup> and a 10% to 36% false-negative rate.<sup>22</sup> Finally, VCE fails to identify the major papilla in a majority of cases<sup>23,24</sup> and therefore may miss important duodenal lesions because of rapid

transit through the duodenal loop. This deficiency may be improved to 60% if a dual camera capsule is used. There are studies to suggest that repeat VCE may be of benefit and increase the diagnostic yield, even when the first VCE study is negative. Diagnostic yield of a repeated VCE was reported to be between 35% and 75% with subsequent management change reported

in 39% to 62.5% of the patients, particularly when the type of bleeding changes from occult to overt or there is a hemoglobin drop greater than 4 g/dL.<sup>25–27</sup> In some patients, luminal debris and bubbles interfere with endoscopic viewing. Some physicians use polyethylene glycol-based preparations, prokinetic agents, simethicone, or a combination of these products before capsule

ingestion; however there is no consensus as to the necessity of a pre-VCE bowel preparation.<sup>1,2</sup>

Some patients may be considered unsuitable candidates for VCE, including patients with cardiac pacemakers, implanted defibrillators, left ventricular assist devices, and patients with suspected small bowel obstruction. Yet, multiple case series suggest that VCE, when performed with careful patient monitoring, is safe in patients with pacemakers and implanted cardiac defibrillators.<sup>28–31</sup> Patients with swallowing disorders or an unwillingness to voluntarily swallow the capsule may have the capsule endoscopically placed into the duodenum. Historically, overtubes have been used to deliver the capsule into the stomach, whereas standard polypectomy snares and nets have been used for capsule delivery directly into the duodenum.<sup>32–34</sup> The AdvanCE (US Endoscopy, Mentor, OH) allows endoscopic delivery of the video capsule. The system is a disposable catheter with a sheath diameter of 2.5 mm that is preloaded through the accessory channel of an endoscope. A specialized capsule cup is screwed onto its distal end, and the activated video capsule is loaded into the cup. The upper endoscope and the device are then advanced to the desired anatomical area, and the capsule is released via a deployment apparatus located at the proximal catheter. Additionally, a capsule paired with a magnetic wand (Navi Capsule, IntroMedic, Seoul, Korea) has been created to assist with mobilizing the device through the esophagus, stomach, and into the duodenum to facilitate delivery in patients with delayed gastric emptying.

Capsule retention is a potential adverse event of VCE.<sup>35</sup> The reported incidence of capsule retention ranges from 0% in healthy volunteers, to 1.4% in patients with obscure GI hemorrhage, to 2.1% in patients with suspected small bowel obstruction due to neoplastic lesions, and up to 2.6% in small bowel Crohn's disease, which limits its use in patients with suspected bowel obstruction or strictures until luminal patency is documented.<sup>36–38</sup> Pre-VCE

screening small bowel radiographs have not been able to eliminate capsule retention. To address the problem of capsule retention, the Agile Patency Capsule (PC) was developed (by Given Imaging, now Medtronic, Minneapolis, MN). The PC, being the same size as a video capsule, serves as dummy to assess the patency of the small bowel prior to VCE examination. As one of the major contraindications for VCE is suspicion of small bowel stenosis, routine administration of PCs could enable safe VCE use in a larger patient population by ruling out possible stenosis.<sup>10</sup> The PC system consists of two main parts: the capsule itself, with a radio frequency identification tag (RFID tag), and an external detector system to capture radio frequency signals. The PC is made of lactose and 10% barium, which dissolves when coming into contact with intestinal fluids through the window located at the edge of the capsule, also known as the timer plug. To ensure that the timer plug is not blocked by capsule impaction in a stricture, the second-generation PCs consist of two timer plugs. If PC excretion does not occur, dissolution starts at 30 hours. After 35 hours, 38% of the capsule is dissolved and is 100% dissolved within 72 hours.<sup>10</sup> After dissolution, the remains of the PC encounter no difficulties in passing a small bowel stricture. One drawback of the RFID tag system is the possibility of impaction in a stricture and resultant small bowel ileus or obstruction. Recently however, the use of a "tag-less" Agile PC was reported by Nakamura et al (2014)<sup>11</sup>

The PillCam SB video capsule endoscope (Medtronic) is a wireless capsule (11 mm × 26 mm) composed of a light source, lens, complementary metal oxide semiconductor imager, battery, and wireless transmitter. The PillCam SB has a battery life of approximately 7 to 8 hours, in which time the capsule captures two images per second (approximately 60,000 total images per examination) in a 140-degree field of view and 8:1 magnification. The smooth outer coating of the capsule allows easy ingestion and prevents adhesion of intestinal contents as the capsule moves via natural peristalsis from the mouth to the anus. Endoscopic images are transmitted via sensor arrays to a recording device worn as a belt by the patient. The recorded images are downloaded into a Reporting and Processing of Images and Data (RAPID) computer workstation and reviewed as a continuous video by the physician. The PillCam SB VCE offers advanced optics and a wider field of view for imaging the small bowel and also provides

Automatic Light Control for optimal illumination of each image. The third generation of PillCam SB (Pillcam SB 3) is now available. CapsoCam by Capsovision (Saratoga, CA) renewed the concept of VCE by offering a capsule with a 360-degree view and on-board image storage, which enables the retrieval of images wire-free after interception of the capsule in the feces. The capsule contains four cameras, which offer high-resolution images and a frame rate up to 20 fps max. Furthermore, two new technologies were developed, Smart Motion Sense Technology and Auto Illumination Technology. Smart Motion Sense Technology enables the capsule to activate its cameras only during capsule motion. When the capsule is stationary, a sensor is used to compare the current frame with the previous frame to control reactivation. Auto Illumination Technology controls the 16 white LEDs to provide the optimal level of illumination. When the capsule is located near the bowel wall, a low light intensity is optimal to capture the best images. A position further away from the wall necessitates a higher light intensity. By adding these software features, battery life is extended up to 15 hours. The first clinical trial that used the CapsoCam reported its safety and efficacy in small bowel evaluation.<sup>12</sup> In a French study by Pioche et al (2014), the concordance between the PillCam SB2 and CapsoCam was evaluated in terms of diagnostic yield and image quality. A kappa value of 0.63 was reported, confirming good concordance between the two capsules. Although the reading time of the CapsoCam was longer, the CapsoCam detected significantly more lesions in a per-lesion analysis.<sup>13</sup> Olympus (Center Valley, PA) has also introduced a next-generation video capsule: ENDOCAPSULE EC-10. With the ENDOCAPSULE EC-10 System, there is improvement in the angle of view, 160 degrees as opposed to 145 degrees in the previous model, battery life has been extended from 8 hours to 12 hours, and there has been an improvement in image quality. Other small bowel capsules with technical features are listed in Table 17.1.

### Device-Assisted Enteroscopy

Deep evaluation of the small bowel can be accomplished with balloon-assisted or non-balloon-assisted enteroscopes coupled with a specialized overtube apparatus. The procedure can be performed via an antegrade approach (via the mouth) or via a retrograde approach (via the anus). In the United States, current

options for device-assisted enteroscopes include double-balloon enteroscopy (DBE), single-balloon enteroscopy (SBE), and spiral enteroscopy. A newer, through-the-scope balloon-assisted device that allows "on-demand" enteroscopy is also available.

DBE, initially described and reported by Yamamoto et al (2004), is a novel endoscopic insertion technique that attempts to improve on currently available endoscopic insertion methods to evaluate the entire length of the small bowel.<sup>44</sup> The DBE system (Fujinon Inc, Saitama, Japan), uses a high-resolution, dedicated video enteroscope that has a working length of 200 cm and two soft, latex balloons; one balloon is attached to the tip of the enteroscope, and the other is attached to the distal end of a soft, flexible overtube (Fig. 17.11). The balloons can be inflated and deflated using an air pump that is controlled by the endoscopist while monitoring air pressure.<sup>45</sup> The balloons grip the wall of the bowel, allowing the endoscope to be advanced without looping.

The procedure can be performed via an oral or anal approach with or without fluoroscopic guidance. Choice of peroral or transanal approach is usually dictated by suspicion of the location of a possible lesion as determined by preceding small bowel VCE or other small bowel imaging technique.<sup>46,47</sup> In a peroral approach, when the two balloons reach the duodenum, the overtube balloon is inflated to fix the overtube to the small bowel wall. The overtube is held in place as the endoscope is further inserted. Once the tip of the endoscope is maximally inserted, the balloon on the tip of the endoscope is inflated, the balloon on the overtube is deflated, and the overtube is advanced over the shaft of the endoscope. When the distal end of the overtube reaches the tip of the endoscope, the overtube balloon is reinflated, again fixing

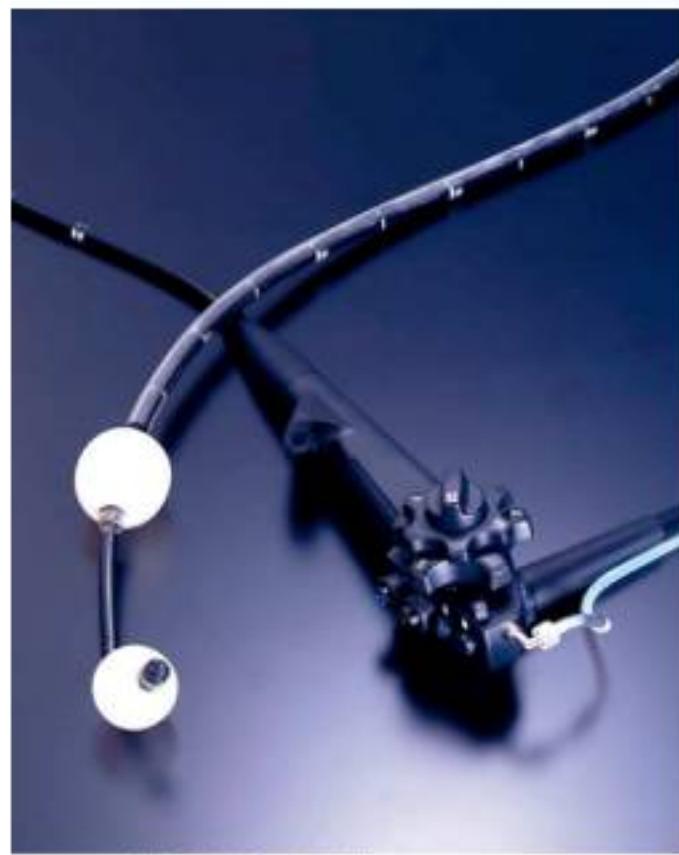

the overtube to a second point on the small bowel wall. This sequence is repeated until the entire small bowel is evaluated or further advancement of the endoscope is unable to be performed.

The mean reported procedure times for DBE range from 73 to 123 minutes. The estimated depth of insertion for the peroral antegrade approach is reported to be between 220 and 360 cm and for the transanal retrograde approach between 120 and 180 cm. Reported rates of complete enteroscopy widely vary. Whereas Japanese studies have reported complete enteroscopy rates in the 70% to 86% range, Western series have generally reported much lower completion rates. Reported DBE diagnostic yields have ranged from 40% to 80%, with therapeutic yields of 15% to 55%.<sup>48-51</sup> In a 2010 study of 200 patients with OGIB bleeding undergoing DBE, the diagnostic yield was 77% for overt bleeding, 67% for patients with occult hemorrhage, and 59% for patients with prior overt bleeding.<sup>52</sup> Moreover, as compared with VCE, DBE has been shown to have similar diagnostic yields in evaluating small bowel disease.<sup>53</sup> Successful performance of endoscopic therapeutic interventions has been reported in 40% to 73% of patients undergoing DBE. Urgent DBE may be better than nonurgent DBE and is associated with a lower recurrent bleeding rate.<sup>54</sup> In addition, one study suggests higher diagnostic yields of DBE for patients with overt bleeding, yet higher recurrence rates in patients presenting with obscure overt bleeding.<sup>55</sup> Moreover, repeat DBE from the same direction may be beneficial, particularly if the patient had a prior positive DBE.<sup>56</sup>

DBE has technical nuances that require specialized training. Furthermore, two operators are needed for the procedure. The procedures are lengthy and potentially uncomfortable for the patient and may be fatiguing for the operators. It is not recommended that both antegrade and retrograde approach procedures be performed on the same day.<sup>57</sup> Antegrade examinations are thought to be easier than retrograde examinations because of difficulty in intubating the terminal ileum via the retrograde approach, with reported failure rates of ileal intubation with retrograde examination ranging from 7% to 30%. Previous abdominal surgery and resultant adhesions can also make the procedure more difficult. The most commonly reported adverse events with DBE include pancreatitis, bleeding, and perforation with an overall rate ranging between 1.2% and 1.6%. Specifically, the rate of pancreatitis is reported to be 0.3% and that of perforation to be between 0.3% and 0.4%. Of note, the perforation risk seems to be higher in patients with surgically altered anatomy, and thus caution is advised in such cases (Videos 17.11 to 17.16).

### Single-Balloon Enteroscopy

SBE was introduced in 2007, and uses a dedicated enteroscope with an overtube (SIF-Q180; Olympus America Inc., Center Valley, PA) and a balloon inflation control device that allows automatic balloon pressure control. In contrast to DBE, only the disposable overtube has a nonlatex balloon at its distal end. The enteroscope has a working length of 200 cm, an outer diameter of 9.2 mm, and a 2.8-mm diameter working channel. The overtube (ST-SB1; Olympus) is 140 cm long with a 13.2-mm outer diameter, and its distal end has an inflatable silicone balloon (Fig. 17.12). The balloon is controlled by pressing buttons on the front panel of the Olympus balloon control unit or on a remote control. The internal surface of the overtube is hydrophilic, and lubrication between the outer surface of the enteroscope and the inner surface of the overtube is facilitated by flushing the internal surface of the overtube with water.<sup>58,59</sup>

**FIG 17.11** Double-balloon enteroscope.

**FIG 17.12** Single-balloon enteroscope.

The technique for SBE is similar to DBE. The overtube is backloaded onto the enteroscope, and the enteroscope is advanced as far as possible into the small bowel, then anchored by using its flexible tip (as opposed to enteroscope tip balloon-assisted anchoring used in DBE). Subsequently, the overtube is advanced with its balloon deflated to the tip of the enteroscope. The overtube balloon is then inflated while keeping the enteroscope tip flexed. Subsequently, the entire apparatus is withdrawn to allow pleating of the small bowel over the enteroscope and overtube. The efficacy of SBE is generally similar to DBE. Reported diagnostic yields have ranged from 41% to 65% and therapeutic yields from 7% to 50%.<sup>51–55</sup> The reported range for depth of insertion is 130 to 270 cm for antegrade examinations and 70 to 200 cm for retrograde examinations. Studies suggest that the rate of total enteroscopy with SBE may be lower than that with DBE by up to 24%. SBE is associated with challenges similar to DBE, but overall, SBE is technically less complicated given that only a single balloon must be inflated and deflated by the endoscopist. However, it has been suggested that, due to a lack of an anchoring mechanism on the enteroscope, there can be difficulty in maintaining the enteroscope position in the small bowel as the overtube is advanced. Similar to DBE, transanal retrograde ileal intubation during SBE can be challenging. The procedure times for antegrade and retrograde approaches are similar, and the overall procedure times are comparable to those of DBE. Adverse events reported with SBE are rare and include abdominal pain, fever, mucosal tears, pancreatitis, and perforation.

### Spiral Enteroscopy

Spiral enteroscopy was also introduced in 2007, with the potential to provide a simpler and faster deep enteroscopy technique compared with balloon-assisted enteroscopy (Video 17.17). Spiral enteroscopy uses a disposable overtube with a soft, raised spiral ridge that is designed to pleat the small bowel. The overtube is 118 cm long with a soft, raised, spiral helix at its distal end that is either 4.5 mm (low profile) or 5.5 mm (standard profile) in height. The overtube is compatible with enteroscopes that are 200 cm in length and between 9.1 mm and 9.5 mm in diameter (Fig. 17.13). Two different overtubes are available for antegrade (Endo-Ease Discovery SB, Spirus Medical LLC, West Bridgewater,

**FIG 17.13** Spiral enteroscope.

MA) or retrograde (Endo-Ease Vista, Spirus Medical) examinations. The overtube has a coupling device on its proximal end that affixes itself to the enteroscope. This allows for free rotation of the overtube independent of the enteroscope but prevents independent movement of the enteroscope (advancement or withdrawal) relative to the overtube.<sup>56–58</sup> A motorized spiral enteroscopy system has been developed by Olympus and early pilot data in a small group of patients was recently reported in abstract form.<sup>59</sup> Spiral enteroscopy is rather simple to perform, and forward progress through the small bowel can be completed in approximately 18 minutes.<sup>60</sup> Based on the prior literature, the mean procedure times for the anterograde approach have been estimated to be  $79 \pm 15$  min for DBE (10 studies),  $65 \pm 16$  min for SBE (5 studies), and  $35 \pm 6$  min for spiral enteroscopy (4 studies). Two operators are required to perform spiral enteroscopy: an endoscopist and an assistant to operate the overtube. Before insertion, the inner lining of the overtube is generously lubricated with the proprietary lubricant supplied with the device. The overtube is then backloaded onto the enteroscope so that approximately 20 cm of the enteroscope protrudes past the distal tip of the overtube. When the overtube and enteroscope are coupled, the overtube should be rotated clockwise for advancement and counterclockwise for withdrawal. For antegrade examination, the overtube and enteroscope are advanced slowly with clockwise rotation of the overtube until the enteroscope tip ideally reaches the ligament of Treitz.

The diagnostic yield of the initial cases of spiral enteroscopy has been reported to be only 33%.<sup>60</sup> More recent prospective data (2011) suggest that the diagnostic yield in patients with a positive VCE study was 57%.<sup>61</sup> Questions have been raised regarding safety concerns with bowel trauma and difficulty in rapid device removal during an emergency. However, there were no major adverse events reported in the early published literature.<sup>62</sup> In a series of 75 patients, 12% reported a sore throat, 27% had superficial mucosal trauma, and 7% had moderate esophageal trauma that did not require intervention. In a retrospective registry study involving 1750 patients, the rate of severe adverse events was reported to be 0.3%, with a small bowel perforation rate of 0.3%.<sup>63</sup>

### On-Demand Enteroscopy

The NaviAid (SMART Medical Systems Ltd, Ra'anana, Israel) is a newer device that consists of a disposable balloon component that is advanced through the working channel of an upper endoscope or colonoscope (NaviAid AB and NaviAid ABC).<sup>70</sup> The NaviAid AB has a working length of 350 cm with a balloon diameter of 40 mm. The minimum endoscope working channel diameter needed for passage of the device is 3.8 mm. The inflation/

deflation of the balloon is controlled by an air supply unit, and balloon pressure is regulated. The balloon device can be advanced through the channel of the endoscope if deep enteroscopy is required "on demand." The NaviAid device requires no specific premounting or preprocedural preparation. The procedure technique is conceptually similar to balloon-assisted enteroscopy. The balloon is advanced beyond the tip of the endoscope through the working channel and inflated to anchor itself to the bowel wall. Subsequently, repetitive push-pull maneuvers are performed with the endoscope sliding over the catheter as a rail until it reaches the inflated balloon distally. The balloon catheter can be withdrawn to allow for therapeutic interventions as needed and reinserted for further advancement of the endoscope. The NaviAid enteroscopy platform is balloon-guided, whereas DBE and SBE are scope-guided and balloon-assisted techniques. Achieving deeper insertion is often better achieved with a scope-guided enteroscopy platform. Preliminary studies of the NaviAid on-demand enteroscopy system report mean antegrade insertion depths of 120 to 190 cm with mean procedure times of 16 to 52 minutes. Data on retrograde examinations have reported a mean depth of insertion of 89 to 110 cm. Diagnostic and therapeutic yields for antegrade examinations are 45% and 36%, respectively, and for retrograde examinations, 59% and 47%, respectively.<sup>70</sup>

Few studies have directly compared DBE, SBE, and spiral enteroscopy. Parameters evaluated have included depths of insertion, rates of complete enteroscopy, procedure times, clinical outcomes, learning curves, and safety.<sup>71–75</sup> Currently, there are no comparative data for the NaviAid on-demand enteroscopy system.

A few studies, with limited numbers of patients, have evaluated the role of emergency DBE in actively bleeding patients.<sup>77–79</sup> Diagnostic yields and short-term outcomes appear to be promising. Deep enteroscopy as an initial diagnostic and therapeutic step in actively bleeding patients is an included consideration in the European Society of Gastrointestinal Endoscopy (ESGE) and American College of Gastroenterology (ACG) guidelines on management of small bowel bleeding.<sup>12</sup>

### Intraoperative Enteroscopy

Exploratory laparotomy with intraoperative enteroscopy (IOE) has been used since the 1980s and is a diagnostic and potentially therapeutic endoscopic modality in suspected small bowel disease; it is also considered the ultimate endoscopic evaluation of the small bowel.<sup>80–83</sup> In addition to being able to diagnose small bowel sources of bleeding, IOE allows for identification of lesions for definitive surgical resection. A colonoscope (pediatric or adult size) or, more optimally, a dedicated small bowel video enteroscope, can be advanced beyond the ligament of Treitz into the proximal jejunum by peroral route or by way of a small bowel enterotomy. The latter technique expedites the examination, especially of the distal small bowel, and minimizes the potential for iatrogenic trauma to the small bowel arising from excessive manipulation of the endoscope that can arise from peroral passage. Once inserted, the surgeon gently telescopes the small bowel over the shaft of the endoscope, allowing for the careful inspection of the mucosa.

Inspection of the small bowel mucosa should be performed in an anterograde manner. When using a small bowel enterotomy, the endoscope is first advanced to the terminal ileum/cecum and then withdrawn with careful inspection. Dimming the operating room lights facilitates endoscopic visualization by the

endoscopist and external inspection of the bowel by the surgeons. Lesions identified endoscopically can be marked for resection by the surgeon with a suture placed on the serosal aspect of the bowel. After completion of the enteroscopy and withdrawal of the endoscope, the marked sites can then be surgically resected. An alternative approach to IOE involves insertion of a sterilized (or sterile-covered) endoscope through multiple, surgically created enterotomies, rectal insertion, or laparoscopy-assisted enteroscopy. Reported adverse events associated with IOE include mucosal lacerations, perforations, prolonged ileus, abdominal abscess, and bowel ischemia.<sup>80–83</sup> Due to its invasive nature and potential for adverse events, the decision to perform IOE must not be taken lightly. All risks and benefits need to be fully considered and explained to the patient; only experienced endoscopists and surgeons should perform this procedure. Currently, this technique is reserved as a last option if deep enteroscopy using DBE, SBE, or spiral enteroscopy cannot be performed successfully because of the presence of abdominal adhesions, obesity, or other technical factors.

## RADIOGRAPHIC IMAGING STUDIES

### Small Bowel Contrast Radiography

A small bowel series (upper GI series with small bowel follow-through) involves the oral ingestion of a dilute barium solution with serial abdominal images obtained of the small bowel. Enteroclysis is a double-contrast study performed by passing a tube into the proximal small bowel and injecting barium, methylcellulose, and air, and is considered superior to standard small bowel follow-through. An upper GI series with small bowel follow-through is sometimes used to evaluate obscure GI bleeding either before performing push enteroscopy or after a negative push enteroscopy examination. The role of small bowel series and enteroclysis in the evaluation of obscure GI bleeding has declined substantially because of its very low diagnostic yield (0% to 6% for small bowel follow-through and 10% to 25% for enteroclysis) and the advent of improved endoscopic diagnostic techniques for the small bowel.<sup>12</sup> In addition to limited diagnostic sensitivity in middle GI bleeding, enteroclysis can be uncomfortable for the patient and involves more radiation exposure than small bowel follow-through. Generally, the role of enteroclysis in the evaluation of middle GI bleeding is limited to settings in which VCE and enteroscopy are unavailable or contraindicated, such as clinical situations that suggest small bowel obstruction secondary to malignancy, Crohn's disease, or prior significant nonsteroidal antiinflammatory drug use. Otherwise, there is little or no role today for either small bowel series or enteroclysis in the evaluation of suspected middle GI bleeding.

### Cross-Sectional Imaging

Novel cross-sectional imaging techniques for evaluation of the small bowel include helical computed tomography enteroclysis (CTE), helical CT angiography, and magnetic resonance (MR) and CT enteroclysis/enterography. In a meta-analysis of 18 studies, CTE had a pooled yield of 40% compared with 53% for VCE.<sup>84</sup> Several studies have shown that VCE has higher yields for detecting vascular and inflammatory lesions compared with CTE.<sup>85,86</sup> However, some studies have shown that CTE can detect vascular and inflammatory abnormalities, which may be missed on VCE.<sup>87</sup> The detection of subtle vascular abnormalities at CTE may be influenced by technique and experience. An advantage of CTE over VCE is the improved detection of small bowel masses,

especially those that are mural-based. In a study by Huprich et al (2011), CTE detected 9/9 (100%) small bowel tumors, whereas VCE only detected 3/9 (33%) of the lesions.<sup>57</sup> Therefore CTE and VCE are complementary examinations. For example, in a study of 30 patients with negative CTE, subsequent VCE was positive in 57%.<sup>58</sup> In another study of 52 patients with nondiagnostic VCE, subsequent CTE had a 50% positive yield in those patients with overt small bowel bleeding.<sup>59</sup> Because of the limited number of studies using MR enterography (MRE), this exam is not routinely recommended in lieu of CTE, but can be considered in patients less than 40 years of age because of absence of radiation exposure.<sup>59,60</sup>

An advantage of cross-sectional small bowel imaging techniques is the ability to screen for contraindications to VCE. In one study, 11% of patients being evaluated for suspected small bowel bleeding were excluded from VCE secondary to high-grade strictures identified on MRE.<sup>61</sup>

### Nuclear Medicine Studies

Tagged red blood cell (RBC) scans are noninvasive, safe, and readily available. Most commonly performed with technetium-labeled RBCs, a radionuclide bleeding scan detects bleeding that is occurring at a rate of 0.1 to 0.5 mL/min. It is of little or no value in patients with suspected, occult, middle GI bleeding who appear to have a low rate of blood loss because the rate of bleeding is too slow to be detected. Bleeding scans may be more sensitive than angiography, but less specific than either a positive endoscopic or angiographic examination.<sup>62,63</sup> Early scans (up to 4 hours after initial injection) may be helpful in gross localization of bleeding when the rate of blood loss exceeds 0.1 to 0.5 mL/min. However, tagged RBC scans can identify only a general area of bleeding, and assessment with other diagnostic modalities, such as angiography, is usually necessary after nuclear scans. The role of nuclear medicine scans is very limited, if at all relevant today in patients with suspected middle GI bleeding, because the ability to accurately localize the source of bleeding is poor at best and better, more readily available technologies exist (e.g., multidetector CT angiography).<sup>64</sup>

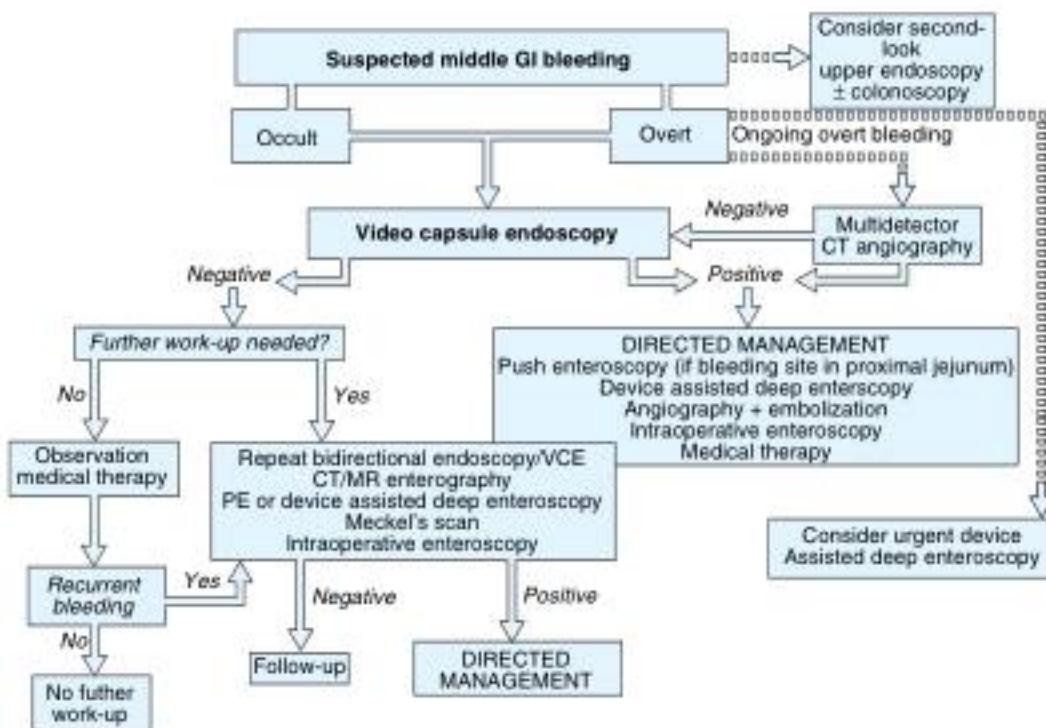

### CT Angiography

Most studies using CT to evaluate GI bleeding are performed during multiphase contrast enhancement with one of the phases occurring during the arterial phase of enhancement. When performed with oral contrast, this is referred to as multiphasic CTE. When no oral contrast is administered, the technique has been termed multiphasic CT or CT angiography (CTA). Multiphasic CT or CTA is usually performed to detect the site of active bleeding in cases of acute overt bleeding, which can occur sporadically or in the setting of small bowel bleeding. CTA has been shown to be able to detect bleeding rates as slow as 0.3 mL/min compared with 0.5 to 1.0 mL/min for conventional angiography and 0.2 mL/min for <sup>99m</sup>Tc tagged RBC scintigraphy. A meta-analysis of nine studies including 198 patients showed CTA had a pooled sensitivity of 89% and specificity of 85% in diagnosing acute GI bleeding throughout the GI tract.<sup>65</sup> Several of these studies demonstrated detection by CTA when other techniques were negative. CTA is widely available and can be performed rapidly during the time of bleeding, which may aid in detection compared with other techniques. CTA has also been shown to accurately localize the site of bleeding.<sup>66</sup> Other studies have shown sensitivities of 79% to 94% and specificity of 95% to 100% for detecting active bleeding throughout the GI tract.<sup>67-69</sup> In a study

of 113 consecutive patients with active GI bleeding, CTA was positive in 80/113 (70.8%), all of which were confirmed. Negative studies were seen in 33 patients (29.2%). Out of the 33 patients, 27 required no further intervention.<sup>69</sup> In a retrospective analysis of 31 patients with suspected overt small bowel bleeding, CTA had a yield of 45% (86% tumor yield and 33% nontumor yield) compared with 94% for DBE. CTA detected one of seven ulcers, six of seven tumors, and both angioectasias seen at DBE. In addition, CTA provided correct guidance for DBE in 100% of cases.<sup>70</sup> CTA can also be used to help triage patients for further management. In one study, 64/86 CTA was negative and 92% of these patients required no further intervention. There were no cases with a negative CTA that had a subsequent positive conventional angiogram within 24 hours.<sup>71</sup> Therefore some have recommended watchful waiting in cases with a negative CTA as the bleeding rate may be low or intermittent and conventional angiography rarely shows an additional site of bleeding. Factors predictive of a positive conventional angiogram following a positive CTA include nondiverticular etiologies and lower hemoglobin levels and should be performed soon after the CTA to enhance detection.<sup>72</sup> To detect contrast extravasation, the patient must be actively bleeding at the time of the scan. The findings of blood within the lumen or sentinel clot may help localize the source if the bleeding is subtle or absent. If no active bleeding or source is identified at the time of the CTA, additional workup may be necessary. In elderly patients with decreased renal function, the administration of intravenous contrast for CT may increase the risk of renal adverse events if subsequent conventional angiography is required.

### Angiography

The data on the clinical utility of angiography in the setting of suspected middle GI bleeding are very limited.<sup>73</sup> Compared with tagged RBC scans, mesenteric angiography is more likely to document the specific site of bleeding, yet the rate of bleeding must be greater than 0.5 mL/min. Angiography can also identify lesions that are not actively bleeding because of demonstration of typical vascular features seen in vascular ectasias (e.g., slow-emptying veins, a vascular tuft, and early-filling veins) and neoplasms. It is possible to administer embolization therapy if an amenable lesion is detected. Provocative angiography using anticoagulants, vasodilators, or thrombolytic agents may increase the likelihood that a source of bleeding can be identified and has been advocated by some investigators.<sup>74,75</sup> However, the risk of inducing uncontrolled bleeding limits the use of this technique and should only be performed at centers with appropriate experience. Throughout the years, catheter-based intervention has shown significant advances with transition from vasopressin infusion to superselective transarterial embolization, resulting in improved results and decreased adverse events. In 15 studies from 1992 to 2006, consisting of 309 patients and using superselective transarterial embolization, there was an 82% technical success rate, 95% overall clinical success rate, 76% 30-day success rate, and a rebleed rate of 12%.<sup>76</sup> However, most cases were for bleeding sources located outside of the small bowel. In a 2014 retrospective study of 70 patients, investigators reported a 99% technical success rate, 71% primary clinical success rate, and 79% secondary clinical success rate after repeat embolization and bowel infarction in 4%.<sup>77</sup> Predictors of failure to achieve 30-day hemostasis included a hemoglobin level of less than 8 g/dL, coagulopathy and upper GI bleeding, contrast extravasation, and more than one vessel needing to be embolized.

### Proposed Diagnostic Strategy

According to the recent ACG and ESGE evidence-based guidelines, we propose similar recommendations for diagnosing a cause of suspected middle GI bleeding (Fig. 17.14).

1. Second-look upper endoscopy should be considered in cases of recurrent hematemesis, melena, or a previous incomplete upper endoscopy exam. Push enteroscopy can be performed as this second-look examination.
2. Second-look colonoscopy should be considered in the setting of recurrent hematochezia, a previous incomplete ileocolonoscopy, or documentation of an inadequate colon preparation at previous colonoscopy.
3. If second-look examinations do not diagnose a bleeding source, the next step should be small bowel evaluation for suspected middle GI bleeding. Unless contraindicated, VCE should be the first-line procedure for small bowel evaluation and before deep enteroscopy to increase diagnostic yield.
4. Device-assisted deep enteroscopy should be attempted if there is a strong suspicion of a small bowel lesion based on clinical presentation or an abnormal VCE study. Any method of device-assisted deep enteroscopy can be used when small bowel endoscopic evaluation and therapy is required.
5. IOE should be limited to clinical situations where deep enteroscopy cannot be performed, such as in patients with prior intraabdominal surgeries and/or intestinal adhesions.
6. Initial "emergency" deep enteroscopy can be considered in cases of massive hemorrhage or when VCE is contraindicated.

### Suspected Overt Middle GI Bleeding

1. In acute, overt, massive GI bleeding suspected to be from the middle GI tract, conventional angiography should be performed emergently for hemodynamically unstable patients.

2. In hemodynamically stable patients with evidence of active bleeding, multiphasic CT (CTA) can be performed to identify the site of bleeding and guide further management.
3. In patients with acute overt GI bleeding and slower rates of bleeding (0.1–0.2 mL/min), or uncertainty of active bleeding, tagged RBC scintigraphy can be performed if deep enteroscopy or VCE are not available to guide timing of angiography.
4. In brisk, active, overt bleeding, CTA is preferred over CTE.
5. Conventional angiography should not be performed as a diagnostic test in patients without overt bleeding. Provocative angiography can be considered in the setting of ongoing overt bleeding and negative VCE, deep enteroscopy, and/or CT, but should only be performed at centers with appropriate experience.
6. In younger patients with ongoing overt bleeding and unremarkable evaluation with VCE and MR/CT enterography examinations, a Meckel's scan should be performed.

## TREATMENT OF SMALL BOWEL VASCULAR LESIONS

### Endoscopic Therapy

Due to its ease of use, availability, and safety, argon plasma coagulation has been the endoscopic treatment of choice for small bowel vascular lesions. To date, there have been no published trials comparing endoscopic therapy of angioectasias compared with sham therapy or trials where only actively bleeding vascular lesions or lesions of a certain size are treated compared with therapy for all visualized lesions. Given these limitations, recurrence of bleeding has been used as a surrogate for the effectiveness of treatment. Two randomized controlled studies demonstrated a lack of benefit for either intervention, VCE versus radiology, or with hormonal therapy compared with placebo.<sup>106,110</sup> A 2014

meta-analysis of 14 studies including 623 subjects with small bowel angioectasia treated with endoscopic therapy demonstrated a pooled rebleeding rate of 34% (95% confidence interval [CI]: 27%-42%) after a mean follow up of  $22 \pm 13$  months.<sup>108</sup> Risk factors for recurrent bleeding from small bowel angioectasia include the overall burden of vascular lesions, age greater than 65 years, jejunal location, presence of concomitant cardiac valvular disease, chronic renal disease, use of anticoagulant medications, and need for blood transfusion. Heyde syndrome is a controversial association between the presence of aortic stenosis and angioectasia and is thought to be secondary to an acquired type 2 von Willebrand's deficiency.<sup>109,110</sup> In support of this association is the fact that some patients with aortic stenosis have demonstrated resolution of GI bleeding after aortic valve replacement.<sup>108</sup> Patients with left ventricular assist devices are also at risk for angioectasias and recurrent bleeding again thought secondary to an acquired von Willebrand's deficiency syndrome.<sup>111</sup>

### Medical Therapy of Middle GI Bleeding

Supportive care with iron, given orally or intravenously, is the mainstay of treatment for mild small intestinal bleeding.<sup>112</sup> This not only helps maintain an adequate hemoglobin level but in more severe cases reduces the frequency of transfusion. In more severe bleeding, transfusion of packed RBCs is an essential element of treatment, particularly when mechanistic and medical methods fail. There are no prospective data showing that withdrawal of anticoagulation therapy is beneficial. In a retrospective study assessing 162 patients with small bowel bleeding, risk factors for recurrent bleeding following DBE included the presence of small bowel vascular disorders and comorbid conditions, but not the usage of anticoagulants or antiplatelet agents.<sup>113</sup>

### Hormonal Therapy

There have been several trials of hormonal therapy, all done in the pre-VCE era. Thus, the precise nature of what was treated was largely unknown with respect to the small intestine. At the present time, hormonal therapy does not have a role in the treatment of small bowel bleeding.

### Somatostatin Analogs

There has been long time interest in the use of somatostatin analogs for treating angioectasias.<sup>114</sup> The proposed mechanism of action for these agents has included reduction of bleeding by the inhibition of angiogenesis, decrease in splanchnic blood flow, increase in vascular resistance, and improved platelet aggregation. Most recently, Nardone et al (2014) performed a retrospective analysis on the use of octreotide in 98 patients with bleeding from angiodysplasia.<sup>115</sup> Over a mean follow-up period of 78 months, the investigators demonstrated a reduction of transfusion requirements. Forty percent of subjects were categorized as complete responders, 32% as partial responders, and 26% as nonresponders. The treatment protocol used was subcutaneous octreotide 100 µg (three times/day) for 1 month; then at 2 weeks, patients received a depot injection of 20 mg monthly for 6 months. Moreover, a 2014 meta-analysis appears to confirm the value of octreotide and its analogs as medical therapy in small bowel angioectasias.<sup>108</sup>

### Thalidomide

Thalidomide is an antiangiogenic agent, thought to be due to its inhibition of vascular endothelial growth factor.<sup>116</sup> It is also an antitumor necrosis factor agent and an immune modulator.

In a randomized, controlled open label trial, including patients with at least six or more bleeding episodes (measured by positive immunoassay fecal occult blood test), subjects received thalidomide 25 mg (four times/day) or 100 mg of daily oral iron.<sup>117</sup> Over a 12-month follow-up period, 20/28 (71%) of patients on thalidomide versus only 1/27 (4%) of patients receiving oral iron had a reduction in bleeding episodes by 50% or more ( $p < 0.001$ ). Adverse events including fatigue, constipation, and somnolence were reported by 73% of the thalidomide group and 34% of the iron cohort. Levels of vascular endothelial growth factor were consistently and significantly lower in the thalidomide treated group. The benefit of thalidomide for patients with small bowel angioectasia failing endoscopic therapy was demonstrated in 9/12 (75%) patients in a study published in 2012 where patients received 200 mg of thalidomide per day for 4 months.<sup>118</sup> Routine use of thalidomide in cases of resistant small bowel bleeding requires further investigation and its use is mostly restricted because of its known teratogenicity.

### Surgical Treatment

Surgical treatment of small intestinal bleeding should be guided by careful IOE whenever possible or by a combination of VCE, deep enteroscopy, and/or angiographic techniques. A combined radiological and surgical option has been reported involving angiographic localization of small bowel vascular lesions.<sup>119</sup> The angiographic catheter is left in place and the patient is transferred to the operating room. At laparotomy, methylene blue is injected via the angiographic catheter. The dye highlights the vasculature and mesentery related to the intestinal lesion allowing for identification and resection of the involved small bowel. Surgery demonstrates excellent results with discrete small bowel lesions, such as tumors or localized arteriovascular malformations. More diffuse lesions, such as multiple angioectasias, are usually treated endoscopically.

## INTRODUCTION

Chronic gastrointestinal (GI) hemorrhage may be overt or occult. Overt bleeding is defined as chronic if it is persistent but not severe enough to cause circulatory compromise. It may be seen in the form of melena or red rectal bleeding. If bleeding is occult, patients may present with symptomatic anemia and evidence of occult bleeding with stool testing. In some patients, chronic hemorrhage may be clinically interspersed with acute episodes.<sup>1</sup> Acute GI bleeding is discussed in detail in Chapters 14–17.

Chronic GI bleeding includes common clinical scenarios, yet the meaning and diagnostic criteria for the different terms are not well delineated.<sup>2</sup> Chronic bleeding from the gut is always significant; in particular, malignant tumors of the gut that are curable may be present. There is no universal agreement regarding the nomenclature of GI lesions that can cause chronic bleeding. Development of new technology, mainly wireless video capsule endoscopy (CE) and balloon-assisted enteroscopy, has provided an opportunity to revisit the traditional classifications of the source of GI bleeding into upper or lower GI bleeding based on the location of the bleeding, either proximal or distal to the ligament of Treitz.<sup>3</sup>

Some authors propose reclassifying GI bleeding into three categories: upper GI, mid-GI, and lower GI bleeding. Bleeding above the ampulla of Vater, within the reach of esophagogastroduodenoscopy (EGD), is defined as upper GI bleeding; small intestinal bleeding from the ampulla of Vater to the terminal ileum, best investigated by CE and balloon-assisted enteroscopy,

is defined as mid-GI bleeding; and colonic bleeding, which can be evaluated by colonoscopy, is defined as lower GI bleeding. A simple classification is presented in Table 18.1. This chapter discusses the evaluation and some of the most frequent causes of occult or unexplained chronic GI bleeding.

Vascular lesions are a common cause of chronic GI bleeding. Arteriovenous malformations (AVMs) of the small bowel account for 30% to 40% of unexplained chronic GI bleeding and are the most common source in older patients. The categorization of vascular abnormalities in the GI tract has been inconsistent and a source of confusion.<sup>4,5</sup> It can be based on histologic characteristics, gross appearance, or association with systemic diseases. These considerations permit categorization into three broad groups, as follows:

1. *Vascular tumors*, which can be benign (e.g., hemangiomas) or malignant (e.g., Kaposi's sarcoma or angiosarcoma).
2. *Vascular anomalies associated with congenital or systemic diseases*, such as blue rubber bleb nevus syndrome, Klippel-Trénaunay-Weber syndrome, Ehlers-Danlos syndrome, pseudoxanthoma elasticum, the CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, scleroderma, and telangiectasias) variant of scleroderma, and hereditary hemorrhagic telangiectasia.
3. *Acquired or sporadic lesions*, such as angiodysplasias, gastric antral vascular ectasia, portal hypertensive enteropathy, radiation-induced vascular ectasias, and Dieulafoy's lesions. Younger individuals (< 40 years of age) most commonly have chronic unexplained bleeding due to Crohn's disease or Meckel's

**Abstract**

Chronic gastrointestinal (GI) hemorrhage may be overt or occult. If bleeding is occult, the clinical presentation is anemia, and evidence of occult bleeding is found on testing of the stools. In some patients, chronic hemorrhage may be clinically interspersed with acute episodes. Chronic bleeding from the gut is always significant; in particular, malignant tumors of the gut that are curable may be present. This chapter discusses some of the most frequent causes of occult or unexplained chronic GI bleeding: vascular tumors, vascular anomalies associated with congenital or systemic diseases, and acquired or sporadic vascular lesions such as angiodysplasias, gastric antral vascular ectasia, lesions related to portal hypertension, and radiation-induced vascular ectasias. An early diagnosis of the bleeding site has become possible recently with the development of several endoscopic modalities for assessment of the small bowel that include wireless capsule endoscopy and deep small bowel enteroscopy (double-balloon enteroscopy, single-balloon enteroscopy, and spiral enteroscopy). Their introduction into clinical practice has revolutionized the evaluation of obscure gastrointestinal bleeding and unexplained iron deficiency anemia. Therapeutic approach for each condition is discussed, focusing on endoscopic management and tips to get the best results with endoscopic treatment.

**TABLE 18.1 Causes of Chronic Gastrointestinal Bleeding**

<b>Gastrointestinal Lesions</b>	
<i>Within Reach of Upper Endoscope</i>	<i>May Be Beyond Reach of Upper Endoscope</i>
Esophagitis	Celiac sprue
Cameron lesions	Crohn's disease
Peptic ulcer disease	Intestinal lymphoma
Gastritis and erosions	Small bowel angiodysplasia
Duodenitis and erosions	Small bowel tumors
Angiodysplasia	Small bowel ulcers and erosions, including NSAID- and other drug-induced lesions
Portal hypertensive gastropathy	Small bowel diverticulosis
Gastroesophageal cancer	Small bowel varices
Gastric or duodenal polyps	Lymphangioma
Gastroduodenal lymphoma	Radiation enteritis
Partial gastrectomy	Blue rubber bleb nevus syndrome
GAVE	Osler-Weber-Rendu syndrome
Dieulafoy's lesion	Small bowel polyposis syndromes Gardner's syndrome Amyloidosis Meckel's diverticulum Hemosuccus pancreaticus, hemobilia Klippel-Trenaunay-Weber syndrome
<b>Colonic Lesions</b>	
Colon polyps	
Colon cancer	
Angiodysplasia	
Colonic ulcers	
Colitis and IBD	
Parasitic infestation	
Hemorrhoids	
Diverticular bleeding	

GAVE, Gastric antral vascular ectasia; IBD, inflammatory bowel disease; NSAID, nonsteroidal antiinflammatory drug.

diverticulum-associated ulceration(s). Small bowel neoplasms (e.g., GI stromal tumor, lymphoma, carcinoid, adenocarcinoma, or other polypoid lesions) and Dieulafoy's lesions can occur in both younger and older patients. Nonsteroidal antiinflammatory drug (NSAID) enteropathy has been associated with mucosal erosions, ulcers, and strictures of the small bowel. Less common causes of unexplained GI bleeding include *Hemosuccus pancreaticus*, *Strongyloides stercoralis* infection, radiation-induced enteritis, and *pseudoxanthoma elasticum*.

## INVESTIGATING CHRONIC UNEXPLAINED GASTROINTESTINAL BLEEDING

Patient age, symptoms, medical/surgical history, physical examination findings, and laboratory data may all provide clues and help guide diagnostic investigations. Recurrent hematemesis indicates bleeding proximal to the ligament of Treitz, whereas recurrent passage of hematochezia without hemodynamic instability usually suggests a colonic source. Melena can originate from a bleeding site located anywhere from the upper GI tract to the right colon.

Thus, a history of melena provides only limited value in terms of localization of obscure GI bleeding. A thorough review of medications may reveal inadvertent use of NSAIDs. A family history of cancer occurring at an early age, particularly colorectal or endometrial, may suggest the presence of hereditary non-polyposis colorectal cancer. Skin, nail, and oral mucosal changes may suggest the presence of several disorders associated with obscure GI bleeding or iron deficiency anemia, including telangiectasias, which may reflect hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome); other conditions with cutaneous and GI manifestations include Kaposi's sarcoma, Peutz-Jeghers syndrome, tylosis, *pseudoxanthoma elasticum*, Ehlers-Danlos syndrome, blue rubber bleb nevus syndrome, Henoch-Schönlein purpura, neurofibromatosis, malignant atrophic papulosis, and Klippel-Trenaunay-Weber syndrome.<sup>1</sup>

## Endoscopic Investigations

### Repeat EGD and Colonoscopy

Second-look upper endoscopy may be helpful in identifying bleeding lesions potentially overlooked or unrecognized at the time of the initial endoscopic evaluation.<sup>7,8</sup> Data suggest that 2% to 25% of lesions causing obscure gastrointestinal bleeding may be overlooked and are within reach of a standard upper endoscope. More recent studies using double-balloon enteroscopy (DBE) and CE have also confirmed these findings.<sup>9-11</sup> Commonly overlooked lesions in the upper GI tract include Cameron's erosions or ulcerations in large hiatal hernias, isolated gastric fundal varices, peptic ulcers, AVMs including gastric antral vascular ectasia (watermelon stomach), and Dieulafoy's lesion. An aorto-enteric fistula should always be considered in patients with prior abdominal aortic aneurysm repair. If second-look upper endoscopy is selected, push enteroscopy may be the chosen method to more thoroughly examine the distal duodenum and proximal jejunum in addition to the more proximal upper GI tract.

Although the reported yield of repeat colonoscopy is low (6%-23%), it may be helpful in selected patients when the original colonoscopy examination was documented to have had a mediocre or poor preparation, the extent of the examination was not to the cecum, the patient is older and risk of a previously missed neoplastic lesion is considered, or the terminal ileum was not previously evaluated. Lesions missed or unrecognized during colonoscopy may include AVMs, polyps, solitary rectal ulcers, rectal varices, and neoplasms.<sup>12</sup>

## ANGIODYPLASIA OF THE GASTROINTESTINAL TRACT

Vascular ectasia of the GI tract, also referred to as angiodysplasia (AD) or less accurately as AVM, is a distinct clinical and pathologic entity.<sup>13-15</sup> It is the most common vascular abnormality of the GI tract and probably the most frequent cause of lower intestinal bleeding in patients older than 60 years. Although the terms *angiodysplasia* and *arteriovenous malformation* have been used synonymously, the term *angiodysplasia* (Greek *angeion*, "vessel"; *dys*, "bad" or "difficult"; *plasis*, "a molding") means a poorly formed vessel but with a lesser connotation of congenital origin than with the word *malformation*. AD are usually distinguished from telangiectasias, which, although anatomically similar, are usually referred to in the context of systemic or hereditary diseases. Because most vascular abnormalities are detected during endoscopy, a classification based on endoscopic appearance has been

proposed.<sup>16</sup> The classification system recognizes the location, size, and number of AD.

### Pathogenesis

AD are composed of ectatic, dilated, thin-walled vessels that are lined by endothelium alone or by only small amounts of smooth muscle. Arteriovenous communications are present because of incompetence of the precapillary sphincter. Enlarged arteries are also present in bigger AD and may be associated with arteriovenous fistulas, which explains why bleeding can be a risk in some patients. Histologic examination shows dilated vessels in the mucosa and submucosa, sometimes covered by a single layer of surface epithelium. The pathogenesis of AD is not well understood. Several theories have been proposed, as follows:

1. AD may develop in response to chronic partial, intermittent, low-grade obstruction of the submucosal veins at the point where they penetrate the muscle layers of the colon.<sup>17</sup> Following this logic, the prevalence of vascular ectasias in the right colon can be attributed to a greater tension in the cecal wall compared with other parts of the colon, according to LaPlace's principle. Over many years, repeated contraction and distention of the cecum results in dilation and tortuosity of the submucosal vein and, later, the venules and capillaries draining into it. Finally, the capillary rings dilate, the precapillary sphincters become incompetent, and a tiny arteriovenous fistula develops.
2. AD may be a complication of chronic mucosal ischemia, which can occur during episodes of bowel obstruction or straining stools.<sup>18</sup>
3. AD may be a complication of local ischemia associated with cardiac, vascular, or pulmonary disease.<sup>19,20</sup>
4. AD may be congenital, which is probably more likely in young patients or patients who have angiodyplasias associated with congenital diseases.
5. Increased expression of angiogenic factors, namely vascular endothelial growth factor (VEGF) and basic fibroblast growth factor, has been demonstrated in human colonic AD and is therefore likely to play a very important role in the development of these lesions as well as in modifying the risk of bleeding.

### Epidemiology and Natural History

The prevalence of GI angiodyplasias in the overall population is not well known, but angioectasias have been seen in 0.2% to 2.9% of "nonbleeding persons"<sup>21,22</sup> and in 2.6% to 6.2% of patients evaluated specifically for occult blood in the stool, anemia, or hemorrhage.<sup>21-25</sup> AD occur most often in the colon, where they are an important cause of lower GI bleeding, particularly in patients older than 60 years of age,<sup>24-26</sup> although presentation in patients in their 30s has been described.<sup>27</sup> There is no gender predilection.

### Clinical Manifestations

AD can remain clinically silent or cause bleeding. The estimated incidence of active GI bleeding in patients with AD is less than 10%. These lesions may be located throughout the GI tract with a variable rate of bleeding associated with them and presentation ranging from hematemesis or hematochezia to occult anemia.<sup>1,28,29</sup> Bleeding is usually chronic or recurrent and, in most cases, low grade and painless.

AD of the stomach have been found to be the cause of blood loss in 4% to 7% of patients with GI bleeding.<sup>28,30</sup> AD in the stomach or duodenum are found incidentally in approximately

50% of cases.<sup>31</sup> The risk that an incidentally found gastric or duodenal AD will subsequently bleed is uncertain. Patients who have bled from gastric or duodenal AD do rebleed. This rebleeding was illustrated in a series of 30 patients with gastric or duodenal AD; 77% had experienced at least one episode of overt bleeding before diagnosis.<sup>32</sup> Approximately 5% of patients presenting with GI hemorrhage have no source found by upper endoscopy and colonoscopy. In approximately 75% of these patients, responsible lesions can be detected in the small bowel. In patients presenting with obscure overt bleeding (defined as the presence of recurrent melena or hematochezia with normal evaluation by upper endoscopy and colonoscopy), small bowel angioectasias are detected in 30% to 60% of examinations.<sup>3,20,32</sup>

The colon is the most common site of AD in the GI tract; colonic lesions are most often found in the cecum and ascending colon. In some reported experiences, AD of the colon account for approximately 20% to 30% of cases of acute lower GI bleeding, approaching the frequency of acute colonic diverticular bleeding.<sup>33</sup> Foutch et al (1995)<sup>34</sup> noted the prevalence of AD to be 0.83% from three prospective studies in which screening colonoscopies were performed in 964 asymptomatic individuals (mean age 61 years) and none of them developed bleeding over a mean follow-up of 3 years.

### Conditions With Increased Prevalence

#### End-Stage Renal Disease

AD is the second most common cause of GI bleeding in patients with end-stage renal disease.<sup>35</sup> These lesions account for approximately 20% of upper GI bleeds and 30% of lower GI bleeds,<sup>35</sup> and approximately 50% of recurrent upper GI bleeds.<sup>36</sup> In a prospective study of upper GI hemorrhage over a 50-month period, vascular ectasia was the etiology of upper GI hemorrhage in 13% of patients with renal insufficiency and was the etiology of bleeding more often in patients with renal insufficiency than in patients with normal renal function.<sup>37</sup> The prevalence of vascular ectasia as a cause of upper GI bleeding was related to the duration of renal failure and the requirement of hemodialysis. Although the reason for the increased prevalence among patients with end-stage renal disease is unknown, a possible explanation is that there is an increased risk of bleeding associated with uremia-induced platelet dysfunction (aggregation and adhesion).

#### von Willebrand's Disease

von Willebrand's disease is a bleeding disorder that results from a qualitative or quantitative defect in von Willebrand factor (vWF). vWF is a complex multimeric glycoprotein present in platelets, plasma, and subendothelium, and is essential to platelet adhesion and aggregation at the site of vascular injury. In a study of patients with both bleeding and nonbleeding angioectasias of the GI tract and control patients with colonic diverticular hemorrhage, Veyradier et al (2001)<sup>38</sup> showed that most patients with bleeding angioectasias of the GI tract lack the largest multimers of vWF induced by a latent acquired form of von Willebrand's disease. Because these specific multimers are the most effective in inducing platelet aggregation in high shear stress that is commonly present in the microcirculation of angioectasias, it was concluded their deficiency contributes to active bleeding.

#### Aortic Stenosis

Approximately 50% of patients with bleeding vascular ectasias have evidence of cardiac disease, and 25% have been reported

**FIG 18.1** **A**, Typical angiodysplasia in the right colon. Angiodysplastic lesions are seen as slightly dilated tortuous vessels. **B**, Angiodysplasia in the stomach. **C**, Narrow-band imaging of the same lesion.

to have aortic stenosis (AS). Bleeding from angiodysplasias in patients with AS (Heyde's syndrome) has been repeatedly reported but is highly controversial.<sup>39</sup> Support for this hypothesis comes from evidence of improvement or cessation of chronic GI bleeding in the vast majority of patients with AS after aortic valve replacement. This effect was sustained for up to 12 years after surgery in the largest case series of 91 patients.<sup>39</sup>

Two possible explanations have been proposed to explain this observation. Patients with AS may develop an acquired form of von Willebrand's disease, which can be reversed after aortic valve replacement.<sup>39,40,41</sup> Patients with AS may be more likely to bleed from existing AD. Another explanation is that existing AD may bleed as a result of ischemic necrosis in patients who have a low cardiac output.<sup>39,42,43</sup> However, this explanation is inconsistent with the observations that bleeding AD have not been observed with other forms of heart disease associated with a low cardiac output and that a low cardiac output is a late complication of AS.

Several retrospective, uncontrolled studies<sup>44,45</sup> and a prospective, controlled investigation<sup>46</sup> do not substantiate a causative role or association of aortic valve diseases with colonic angioectasias. Replacement of the aortic valve for control of bleeding secondary to these vascular lesions is not universally accepted.<sup>47</sup> A logical approach to patients with both lesions is to treat the colonic lesion first endoscopically, regardless of whether the patient's cardiac status warrants surgery. If valve replacement is necessary and endoscopic therapy is unsuccessful, further endoscopic or surgical treatment of the colonic AD should be delayed until after cardiac surgery. Further attempts at endoscopic treatment or surgical resection are indicated if bleeding recurs.<sup>47</sup>

### Progressive Systemic Sclerosis

Vascular lesions are a prominent feature of progressive systemic sclerosis, especially in the CREST variant.<sup>48</sup> In patients with progressive systemic sclerosis, sites most frequently affected by telangiectasias are the hands, lips, tongue, and face, but gastric, intestinal, and colorectal lesions have been reported. These lesions may be the source of occult or clinically significant bleeding and are best treated by endoscopic coagulation.<sup>49</sup>

### Left Ventricular Assist Devices

Patients with left ventricular assist devices have higher rates of GI bleeding, most commonly from angioectasias in the upper digestive tract and small bowel.<sup>50</sup>

**TABLE 18.2 Lesions Confused With Angioectasias on Endoscopy**

Vascular	Nonvascular	Colitis

### Diagnosis

#### Endoscopic Imaging: Standard Upper Endoscopy and Colonoscopy

Angioectasias have a characteristic appearance of a cherry-red, fern-like pattern of arborizing, ectatic blood vessels radiating from a central vessel (Fig. 18.1). This pattern should be specifically looked for because angioectasias may be confused with other erythematous mucosal lesions or with normal vessels (Table 18.2).<sup>20,51</sup> Because traumatic and endoscopic suction artifacts may resemble vascular lesions, all lesions must be evaluated immediately on insertion, rather than during withdrawal. "Anemic halos" are often seen surrounding angioectasias of the bowel. Although these halos do not differentiate the various types of vascular lesions, they distinguish true vascular lesions from artifacts.<sup>47</sup> Newer alternative imaging options, such as narrow-band imaging, allow precise discrimination of vascular structures from artifactual mucosal hemorrhage. Punch biopsy samples of vascular lesions obtained during endoscopy are usually nonspecific; the bleeding induced by performing biopsies of these abnormalities is not justified.

Angioectasias may be difficult to visualize during colonoscopy in patients who do not have an optimal bowel cleaning. Because the appearance of angioectasias is influenced by blood pressure, blood volume, and state of hydration, these lesions may not be evident in patients with severely reduced blood volumes or who are in shock until red blood cell and volume deficits are corrected. Cold water lavage of the colon, as is sometimes done to clean the luminal surface from debris during colonoscopy, reportedly may mask these lesions.<sup>52</sup> Meperidine also has been implicated

in masking lesions because of a transient decrease in mucosal blood flow. Minimizing use of meperidine and reversal with naloxone to increase the yield of detection has been advocated by some clinicians. Naloxone has been reported to enhance the appearance of normal vasculature in approximately 10% of patients and to cause angioectasias to appear (2.7%) or increase in size (5.4%).<sup>30</sup> Reversal of narcotic analgesia may affect the comfort of an examination, particularly if therapeutics are performed.

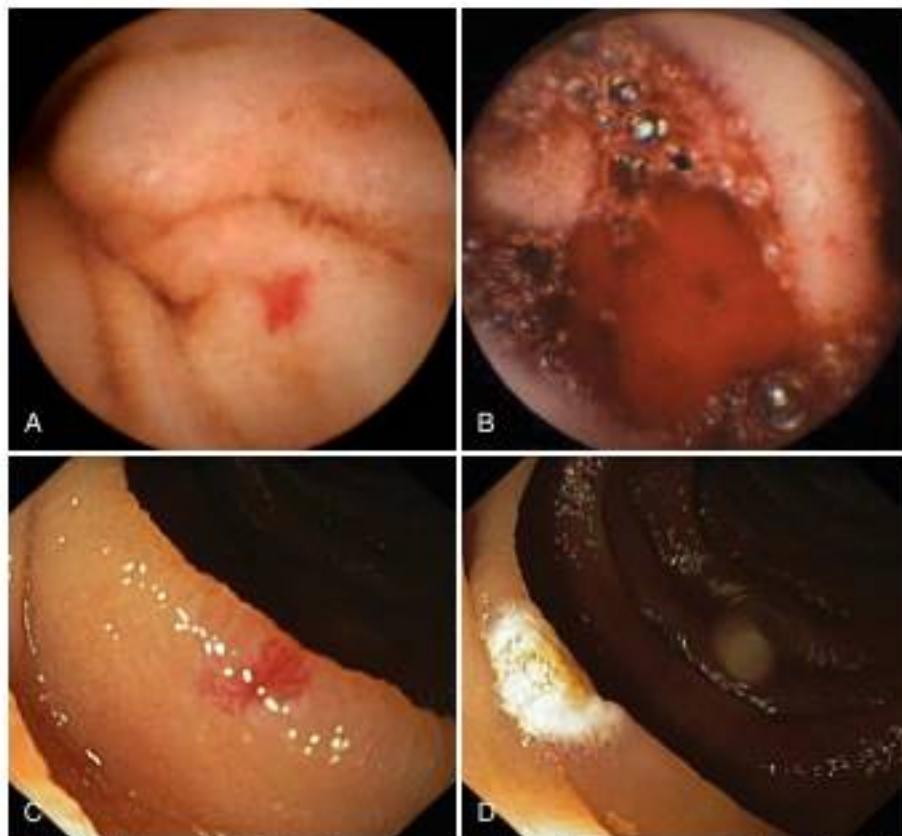

#### Assessment of the Small Bowel

Some patients presenting with GI bleeding have no source found by upper endoscopy and colonoscopy, even after second-look endoscopy.<sup>3</sup> In these cases of unexplained chronic GI bleeding, endoscopic examination of the small bowel has been limited by several factors. The length of the small intestine, in addition to its free intraperitoneal location, vigorous contractility, and overlying loops, confounds the usual diagnostic techniques, including barium studies, endoscopic intubation, and identification of specific sites by special imaging techniques of nuclear medicine scans and angiography. The bleeding rate may be slow or intermittent, not allowing identification by either angiography or radionuclide bleeding scan. Because of the inability to localize a bleeding site in the small bowel, patients with obscure GI bleeding from a small bowel source typically presented with prolonged occult blood loss or recurrent episodes of melena or maroon stool without a specific diagnosis. In this group of patients, previous noninvasive tests, such as small bowel follow-

through, radioisotope-labeled red blood cell scan, and push enteroscopy, have had suboptimal diagnostic yields of 20% to 40%. Invasive methods, such as laparotomy or intraoperative enteroscopy, may improve the yield up to 70%.<sup>31</sup>

An early diagnosis of the bleeding site has become possible recently with the development of several endoscopic modalities for assessment of the small bowel that include wireless CE and deep small bowel enteroscopy (DBE, single-balloon enteroscopy, and spiral enteroscopy [SE]).

When performing a second-look endoscopy, useful adjunctive diagnostic maneuvers include use of a cap-fitted endoscope to examine blind areas, such as the high lesser curve, under the incisura angularis, and the posterior wall of the duodenal bulb; use of a side-viewing endoscope to examine the ampulla in patients with suspected pancreaticobiliary pathology; and use of a push enteroscope to examine the C-loop of duodenum carefully after injection of glucagon. Although the yield is low (6%), repeat colonoscopy may be useful in the setting of prior poor bowel preparation. Use of naloxone may improve the detection of colonic angioectasias that were not obvious at the index examination.<sup>3</sup> When all the findings on standard examinations (upper endoscopy and colonoscopy) are negative, the small bowel may be presumed to be the source of blood loss. CE should be the third test in the evaluation of patients with GI bleeding (Fig. 18.2). CE, balloon, and spiral enteroscopy, as well as other diagnostic modalities for suspected small bowel bleeding, are discussed in detail in Chapter 17: Middle Gastrointestinal Bleeding.

**FIG 18.2** Small bowel angiomyolipomas in patients with obscure gastrointestinal bleeding. **A**, Nonbleeding angiomyolipoma diagnosed by wireless capsule endoscopy. **B**, Active bleeding angiomyolipoma visualized by capsule endoscopy. **C**, Small bowel angiomyolipoma seen with balloon enteroscopy. **D**, Same lesion treated with argon plasma coagulation.

### Diagnostic Algorithm for Endoscopy in Suspected Middle Gastrointestinal Bleeding

Similar to other authors, we recommend<sup>25–27</sup> CE as a first-line investigation over balloon-assisted enteroscopy in view of its convenience, higher chance to visualize the entire small intestine, and similar diagnostic yield. A recent updated and revised meta-analysis of 10 studies involving 642 patients demonstrated that the pooled overall diagnostic yield for video CE (VCE) and DBE was 62% and 56%, respectively.<sup>28</sup> The diagnostic yield of DBE was significantly higher when performed after a positive VCE compared with negative VCE (75% vs. 27.5%). No test substitutes for good clinical judgment, however, and all small bowel diagnostic studies must be considered in difficult cases of obscure GI bleeding, particularly in a young patient.<sup>29</sup>

In the setting of unexplained overt GI bleeding, CE should be performed close to the bleeding episode. In case of negative CE, we recommend that a second endoscopist reread the CE study. We also recommend a second-look EGD with special attention to areas less optimally examined by CE, especially the duodenum, before concluding with a final diagnosis of obscure GI bleeding. Second-look CE has also been suggested for patients with a prior nondiagnostic CE. Bar-Meir et al (2004)<sup>30</sup> reported that 7 out of 20 patients (35%) who underwent second-look CE had positive or suspicious findings. Another study showed that patients with a nondiagnostic CE test would benefit from a second-look CE if the bleeding presentation changed from occult to overt, or if the hemoglobin value decreased 4 g/dL or more.<sup>31</sup>

### Management

The natural history of colonic angioectasias is benign in healthy, asymptomatic individuals, and the risk of bleeding is small.<sup>32</sup> It is estimated that only approximately 50% of colonic lesions ever bleed. There is a risk of bleeding and perforation following attempts at endoscopic obliteration. For all these reasons, in incidentally found angioectasias at all levels of the gut, endoscopic therapy is not warranted.<sup>32</sup>

### Pharmacologic Treatment

Pharmacotherapy should be considered whenever endoscopic therapy, surgical intervention, or angiographic therapy is impractical or ineffective, such as in patients in whom the source and the etiology of bleeding are unknown or the pathology is too diffuse to be amenable to ablative therapies.

Nonbleeding AD detected during evaluation of occult bleeding or iron deficiency anemia should be considered to be causative, if no other cause is found. In patients with occult bleeding, bleeding from AD may be more likely in patients who have multiple lesions and a bleeding diathesis (e.g., anticoagulation). As a result, a graduated approach with primary or adjunctive iron-replacement therapy may be initiated, with pursuit of more aggressive therapeutic options guided by the clinical circumstances.<sup>33–35</sup> The aims of iron-replacement therapy should be to restore hemoglobin levels and mean corpuscular volume to normal, and to replenish body stores.

Numerous oral iron preparations are available, although ferrous sulfate and ferrous gluconate are the preferred forms because of low cost and high bioavailability. A liquid preparation is often tolerated better. Ascorbic acid enhances iron absorption. Parenteral iron should be used when there is intolerance to at least two oral iron preparations or noncompliance, when there is a suboptimal clinical response secondary to suspected iron malabsorp-

tion, and when blood transfusion becomes difficult to achieve because of excessive antibodies that challenge crossmatching.

Estrogen-progesterone combination hormonal therapy has been used to treat patients with angioectasias of the GI tract.<sup>36–38</sup> The effect, which is not immediate, seems to be estrogen dose-dependent. Hormonal therapy acts by enhancing microvascular circulation, coagulation, and vascular endothelial integrity. The most common combination schedule has been ethinyl estradiol 0.01 to 0.05 mg and norethisterone 1 to 3 mg. This therapy should be used in 6-month courses with pauses to reduce the incidence of adverse effects, mostly secondary to the estrogen component. The results of several prospective, controlled trials examining hormonal therapy have been divergent.<sup>36–38</sup> In a long-term observational study, combination hormonal therapy was shown to stop bleeding in patients with occult GI bleeding of obscure origin, likely to have resulted from small bowel AD.<sup>39</sup> Although uncontrolled studies suggest that combination estrogen-progesterone therapy prevents bleeding episodes secondary to AD, the evidence from the largest placebo-controlled trial to date suggests that this therapy is ineffective.<sup>31</sup> These authors considered that efficacy of hormonal therapy in these patients remains to be proven by a large, randomized, placebo-controlled trial with long-term follow-up.

Reports of efficacy of octreotide in the treatment of AD have been limited to case reports and small series in which a response has been reported in some patients.<sup>40–42–44</sup> Octreotide produces vasoconstriction secondary to inhibitory effects on growth hormone and multiple GI vasodilator hormones, and markedly reduces splanchnic blood flow. Its antiangiogenic properties have been shown in different tissues (eye, placenta, liver, and GI neuroendocrine tumors); however, applicability and utility in obscure GI bleeding remain unknown.

The dosage of octreotide can be tapered to the lowest quantity that prevents rebleeding. Response is immediate, and the drug can be administered intravenously (50 µg/hr) or subcutaneously (50–100 µg two or three times a day).<sup>45</sup> Its subcutaneous administration and its longer half-life (90–100 minutes) make octreotide superior to somatostatin and allow use in the outpatient setting. A 6-month course of therapy has been used to treat most patients. A meta-analysis reported by Jackson and Gerson in 2014 including four studies with a total sample size of 77 patients concluded that there is a significant effect on bleeding cessation rates for the somatostatin analogs with a pooled odds ratio of 14.52 (95% confidence interval [CI]: 5.9–36).<sup>46</sup> The standard mean reduction in number of transfusions after 1 year of therapy was 0.55 (95% CI: 0.29–0.82). However, it is difficult to ascertain whether this represents the true effect of octreotide, as this meta-analysis had some inherent weaknesses.<sup>46</sup>

Sandostatin LAR Depot (Novartis Pharmaceuticals Corporation, East Hanover, NJ) is a depot formulation of octreotide for long-term maintenance therapy currently approved for acromegaly and GI and pancreatic neuroendocrine tumors. Compared with conventional octreotide, Sandostatin LAR Depot is administered at a dose of 20 mg intramuscularly once a month with a similar efficacy and safety profile.<sup>46,47,48–50</sup> Sandostatin LAR Depot does not require hospital admission, which makes it an attractive outpatient option for long-term therapy in patients with chronic GI bleeding, but is more expensive than conventional octreotide.

Thalidomide is a drug with powerful immunomodulatory, antiinflammatory, and antiangiogenic effects that was withdrawn from the market in the 1960s because of its teratogenicity. It has been reintroduced more recently and has been demonstrated to

inhibit VEGF-dependent angiogenesis. Thalidomide administered orally at a variable dose of 100 to 300 mg/day is an innovative and promising therapeutic option for GI bleeding associated with AD and can be used in refractory cases or when other drugs or therapies are contraindicated.<sup>65</sup> Thalidomide is contraindicated in patients with peripheral neuropathy and pregnant women and women with childbearing potential because of its teratogenic effects, and it should be used cautiously in patients with cardiovascular or neurologic disorders and hepatic or renal impairment. Owing to its immunosuppressant activity by blocking tumor necrosis factor, use of thalidomide may also be discouraged in patients at risk for infection or chronic infectious disease, especially patients with HIV infection. In all these clinical settings, Sandostatin LAR Depot may be safer than thalidomide.

Two recent studies explore the use of thalidomide for gastrointestinal angiodysplastic lesions (GIADs) in a series of patients. The first study from China in 2011 randomized patients to 100 mg of thalidomide versus iron therapy for 4 months and demonstrated efficacy when rebleeding rates and transfusional requirements were analyzed.<sup>70</sup> The second study from Spain treated 12 refractory patients and demonstrated an increase in hemoglobin values after 4 months.<sup>71</sup>

Other agents that have been used for management of angiectasias with limited available data include tranexamic acid, danazol, desmopressin, and recombinant activated factor VII.

### Endoscopic Treatment

The goal of endoscopic therapy is thrombosis of the bleeding vessel. Studies directly comparing the effectiveness of the different approaches have not been performed. The approach depends on the location of the lesion, the experience of the endoscopist, and the availability of equipment.

**Bipolar or heater probe coagulation.** Bipolar devices deliver heat via a current that flows between the two electrodes at the tip of the probe. This limits the maximum temperature generated, as well as the depth and surface area of tissue injury. Bipolar or heater probe coagulation is said to be effective for treatment of AD,<sup>1,2,3</sup> and these modalities have replaced monopolar coagulation.<sup>10</sup> The choice between argon plasma coagulation (APC) and bipolar coagulation depends on availability and local expertise.<sup>20</sup> Both techniques should be used with caution in the duodenum and ascending colon.

**Sclerotherapy.** Injection of a sclerosant, such as ethanolamine, has been used to obliterate lesions.<sup>11</sup> Epinephrine injection works by volume tamponade of the bleeding vessel and transient vasoconstriction, but should probably be avoided, however, because of the risk of bleeding, ulceration and perforation.<sup>17,34</sup>

**Band ligation.** Band ligation has been used to treat angiectasias of the stomach.<sup>1,2,5</sup> The walls of the small and large intestine above the rectum (especially the right colon) are thinner than the stomach. For this reason, band ligation therapy cannot be advocated owing to the recognized risk for perforation.<sup>17,38</sup>

**Endoscopic resection.** There are some cases reported of polypoid colonic AD treated by polypectomy using a polyloop ligation device in one case with no complications.<sup>39</sup>

**Lasers.** Argon and neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers have been used in the past.<sup>20-21</sup> These techniques require expensive equipment and specific training. More convenient and safer coagulation options have replaced laser therapy.

**Endoscopic clips.** This approach has shown safety and efficacy in few case reports using endoscopic clipping for bleeding colonic AD<sup>30</sup> either as a monotherapy or in combination with

thermal ablation using APC and contact probes. Clipping may be particularly useful in cases of isolated and relatively large lesions to obliterate the feeding vessel and reduce the risk of precipitating bleeding from subsequent electrocoagulation. It can also be useful in patients with high risk of bleeding due to drugs or coagulation defects.

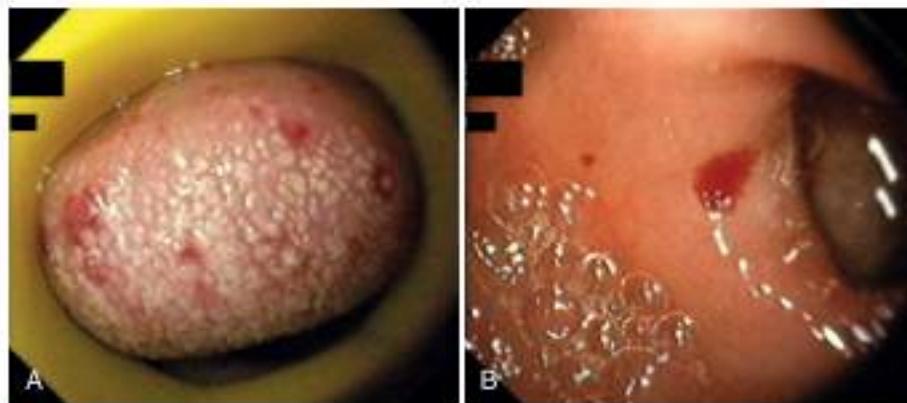

**Argon plasma coagulation.** APC is a monopolar electrosurgical procedure in which electrical energy is transferred to the target tissue using ionized and conductive argon gas (argon plasma).<sup>20</sup> APC seems to be most effective in the treatment of vascular lesions.<sup>20,34</sup> Its great advantage is the limited depth of tissue injury and low cost. Shallow tissue injury is due to the fact that the argon stream always seeks electrically conductive areas of tissue, avoiding the coagulated zones, which have lost their electrical conductivity as a result of desiccation. Before APC, it is recommended to collapse the lumen partially while maintaining the treatment site in view. It is important to avoid thinning of the colonic wall with excessive air insufflation because this increases the risk for perforation during therapy, especially in the cecum.<sup>20</sup>

**Cryotherapy.** Endoscopic cryotherapy allows circumscribed tissue destruction by freezing. Three- to four-second impacts create a 2- to 10-mm large ice layer around the probe tip on the surface of the mucosa. Safety and efficacy of cryotherapy have been reported for treatment of diffuse mucosal lesions of the GI tract.<sup>20</sup>

**Tips to get the best results with endoscopic treatment of GIAD.** The effectiveness of endoscopic treatment of angiectasias is difficult to assess owing to the absence of prospective controlled trials. Endoscopic treatment of vascular lesions in patients known to have coagulation disorders carries an increased risk of procedure-induced hemorrhage.

When treating large lesions, some experienced endoscopists recommend<sup>47</sup> to first ablate the periphery of the lesion to create a collar of edema that theoretically reduces the vascular supply to the lesion and diminishes the potential for immediate or delayed hemorrhage. Some clinicians have placed mechanical clips around the margins of large lesions also to reduce the blood supply and facilitate effective coagulation. Others typically target the central portion of the AD because ensuing coagulation and edema obstruct the peripheral branches and limit the extent of coagulation needed. In addition, for a very large AD, epinephrine injection may contract the lesion and reduce the amount and area of coagulation needed for eradication.<sup>44</sup> In our experience, prior submucosal injection of normal saline can prevent unexpected deep thermal injury from coagulation therapy, especially in areas with a thin wall. Recurrent bleeding can be expected in approximately 20% of patients with colonic angiectasias and in a greater percentage of patients with associated coagulopathies, renal failure, portal hypertension, or additional upper GI vascular lesions.<sup>47</sup> It is reasonable to attempt endoscopic therapy in patients with accessible lesions despite various coexisting morbidities that may allow only short-term success. Patients with multiple lesions or an underlying bleeding diathesis are less likely to benefit long term from endoscopic therapy and are at increased risk of complications, especially delayed bleeding from treatment site thermally induced ulceration. Such patients benefit from any attempts to improve their underlying bleeding tendency.

In preparation for endoscopic ablation of vascular lesions, aspirin, NSAIDs, anticoagulants, and antiplatelet agents should be withdrawn at least 1 week to 10 days before the procedure, when feasible. After therapy, patients must be cautioned not to resume full doses of anticoagulants or antiplatelet agents for at least 1 week if clinically possible. Coagulated tissues are at their

**FIG 18.3** Hereditary hemorrhagic telangiectasia or Rendu-Osler-Weber syndrome. Patient with multiple telangiectasias involving **A**, the tongue and **B**, the stomach.

maximum of thermal injury by 5 to 10 days, and the onset of hemorrhage may be delayed.

### HEREDITARY HEMORRHAGIC TELANGIECTASIA

Hereditary hemorrhagic telangiectasia, or Rendu-Osler-Weber disease, is an uncommon, autosomal dominant disorder characterized by telangiectasias and AVMs that affect many organs, including the skin, periungual areas, lips, oral and nasopharyngeal membranes, tongue (Fig. 18.3A), lungs, GI tract (see Fig. 18.3B), liver, and brain,<sup>30,37</sup> and can result in bleeding. In these vessels, no elastic lamina or muscular tissue is present, so they cannot contract; this property may explain why these lesions tend to bleed.<sup>38</sup>

Mucocutaneous and GI telangiectasias develop progressively with age.<sup>39</sup> Severe GI bleeding is unusual before the 5th or 6th decade<sup>39</sup>; occurs in 25% to 33% of patients with hereditary hemorrhagic telangiectasia; is challenging to treat; and can cause significant morbidity, resulting in severe anemia and high blood transfusion requirements.<sup>103,105</sup>

Endoscopy may reveal telangiectasias in the stomach (see Fig. 18.1B), duodenum, small bowel, or colon that are punctiform, discrete, red spots or with a classic fern-like border similar to all other angioectasias. Lesions are usually flat, although they may be slightly raised 1 to 3 mm, similar in size and appearance to angioectasias of the nasal and oral mucosa.<sup>40</sup> Telangiectasias are more common in the stomach, duodenum, or jejunum than in the colon.<sup>40</sup> They may also have a characteristic pale mucosal halo. CE contributes significantly to defining the extent of small intestinal telangiectasias and can be used to stage the disease to decide on the extent and form of endoscopic therapy.<sup>41</sup> Endoscopic therapy is the most effective form of treatment in stopping hemorrhage from actively bleeding lesions and has reduced the need for emergency bowel resection. Because of the multiplicity of lesions and the redevelopment of lesions, sometimes within weeks, bleeding recurs at varying intervals after therapy, depending on the extent and thoroughness of ablative therapies.<sup>42</sup> Selective mesenteric arteriography may localize the precise bleeding site, but in most cases this is unnecessary.<sup>103</sup>

### GASTRIC VASCULAR LESIONS IN PATIENTS WITH CIRRHOSIS

After variceal bleeding, hemorrhagic gastritis is the most frequent cause of upper GI bleeding in cirrhotic patients with portal

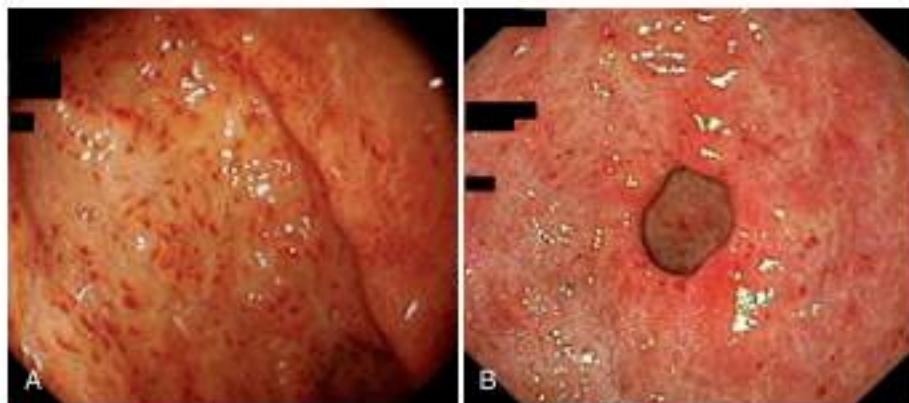

hypertension.<sup>104</sup> The term *hemorrhagic gastritis* has included bleeding from various nonvariceal mucosal lesions, such as multiple ulcerations, portal hypertensive gastropathy (PHG), and gastric antral vascular ectasia (GAVE).<sup>104–106</sup> PHG and GAVE can cause acute and chronic upper GI blood loss.<sup>107</sup> These conditions frequently, but not invariably, are diagnosed by upper endoscopy. Although they are fairly prevalent, only 15% to 20% of affected individuals experience symptomatic GI blood loss.

#### Portal Hypertensive Gastropathy

PHG describes the endoscopic appearance of gastric mucosa, with a characteristic mosaic-like pattern with or without red spots, seen in patients with cirrhotic or noncirrhotic portal hypertension. The mosaic-like pattern appears as a white reticular network separating areas of raised red or pink mucosa, resembling the skin of a snake (*snakeskin appearance*). PHG is seen mainly in the body and the fundus of the stomach, but is also seen rarely in the gastric antrum (Fig. 18.4). When PHG is severe, it can include discrete cherry-red spots, fine pink speckling, or scarlatina-type rash, collectively called *red marks*.<sup>108</sup> The characteristic histologic finding of PHG is dilated capillaries and venules in the mucosa and submucosa without erosion, inflammation, or fibrinous thrombi.<sup>109</sup>

#### Classification

There is no general consensus on the endoscopic classification of PHG. The most widely used classification is the one recommended by McCormack et al (1985),<sup>109</sup> who classified PHG into mild and severe (Table 18.3). Mild PHG is defined by the presence of only a mosaic-like pattern, whereas severe PHG is diagnosed when red point lesions, cherry-red spots, or black-brown spots are present. The popularity of this classification relates in part to its simplicity and its ability to predict the risk of bleeding, with an increased risk of gastric hemorrhage in severe cases (38%–62%) compared with mild cases (3.5%–31%).<sup>103,106</sup> Observed endoscopic findings are often of an intermediate severity, however, and are not well represented as being either mild or severe. Tanoue et al (1992)<sup>110</sup> and the New Italian Endoscopy Club<sup>111</sup> have described a more detailed scoring system. Tanoue et al (1992)<sup>110</sup> classified PHG into four grades (grade 0 = none, grade 1 = mild, grade 2 = moderate, grade 3 = severe). This grading permits more informative description of the observed endoscopic findings. A simpler classification system such as recommended by McCormack et al (1985)<sup>109</sup> has a better intraobserver and interobserver agreement and reproducibility.<sup>112</sup>

**FIG 18.4** Portal hypertensive gastropathy with mosaic pattern and cherry-red spots in **A**, the body of the stomach and **B**, localized in the antrum of a cirrhotic patient.

**TABLE 18.3 Classification of Portal Hypertensive Gastropathy**

McCormack et al. <sup>103</sup>	Tanoue et al. <sup>104</sup>	Primignani et al (NIEC) <sup>102</sup>
<b>Mild</b>	<b>Grade I</b>	<b>Mosaic Pattern</b>
Fine pink speckling (scarlatina-type rash)	Mild reddening	Mild—diffuse pink areola
Superficial reddening	Congestive mucosa	Moderate—flat red spot
Mosaic pattern		Severe—diffuse red areola
<b>Severe</b>	<b>Grade II</b>	<b>Red Mark Lesion</b>
Discrete red spots	Severe redness and fine reticular pattern separating areas of raised edematous mucosa	Discrete
Diffuse hemorrhagic lesion		Confluent (diffuse)
	<b>Grade III</b>	<b>Black-Brown Spot</b>
	Point bleeding + grade II	

NIEC, New Italian Endoscopic Club.

Further work needs to be done to improve the currently available grading system.

#### Prevalence and Risk Factors

The reported prevalence varies widely in patients with portal hypertension (20%–75%) and also in patients with cirrhosis (35%–80%) because of patient selection, absence of uniform criteria and classification, and, more importantly, the differences in interobserver and intraobserver variation.<sup>113,114</sup> Although different studies have yielded mixed results, sometimes contradictory, the preponderance of data<sup>113</sup> suggest that (1) the severity of portal hypertension is associated with the severity or frequency of PHG; (2) the frequency of PHG is higher in portal hypertension with cirrhosis than in portal hypertension without cirrhosis; (3) the underlying etiology of cirrhosis does not affect PHG frequency

or severity; (4) duration of liver disease positively correlates with development of PHG; (5) severity of cirrhosis, as measured by Child-Pugh score, is correlated with frequency of PHG. There is general agreement that the prevalence of PHG increases with variceal obliteration.<sup>115</sup> However, some investigators believe that the higher rate of PHG in patients undergoing endoscopic variceal sclerotherapy merely reflects a longer duration of portal hypertension, more advanced liver disease, or more severe portal hypertension in patients selected to undergo variceal sclerotherapy compared with controls rather than the performance of sclerotherapy per se.<sup>116,117</sup>

#### Natural History and Complications

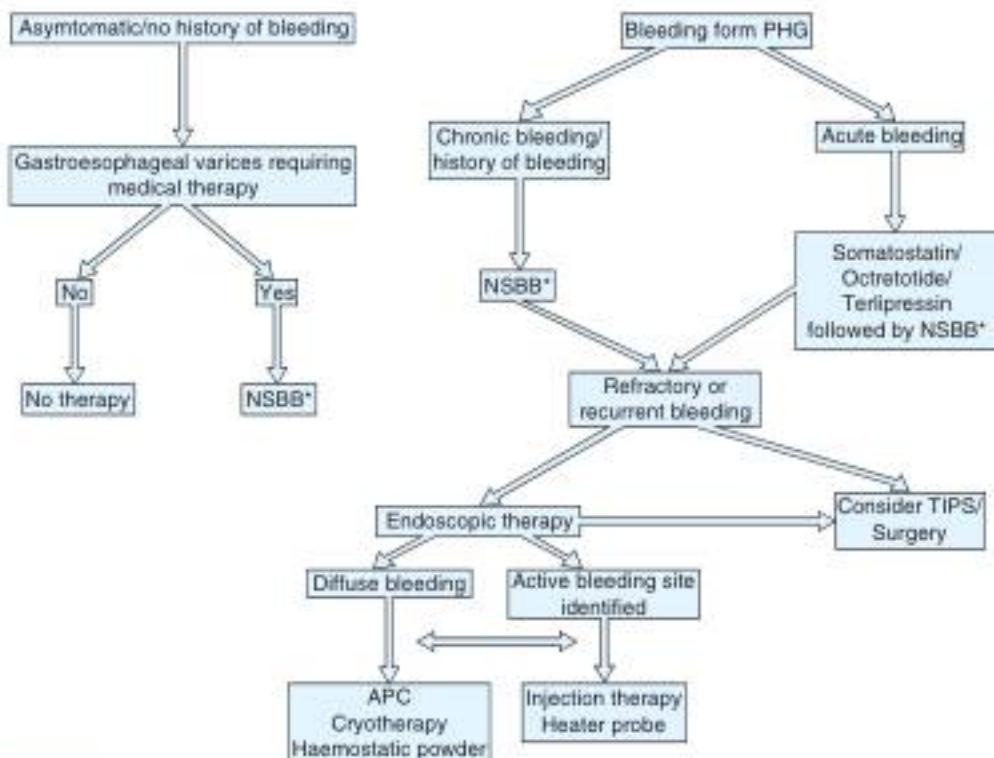

The overall incidence of acute bleeding from PHG is low, and acute bleeding is seen mostly in patients with more severe PHG. Bleeding is often mild, and transfusion requirement is usually limited to 1 to 2 units of blood. The prevalence of chronic bleeding cannot be reliably estimated because of the uncertainty of making a firm diagnosis. Major determinants of bleeding from PHG are length of time the patient had PHG and the extent and severity of lesions. The mortality associated with bleeding from PHG is very low because most bleeds are minor compared with variceal bleeding. Screening for PHG is currently not recommended in patients with liver disease.<sup>113</sup>

#### Management

Management of PHG is centered on reduction in portal pressure, largely through the use of medical rather than endoscopic means.

**Pharmacologic treatment.** The aim of pharmacologic treatment is (1) to control hemorrhage in patients with actively bleeding PHG and (2) to prevent rebleeding in patients with known PHG. Primary prophylaxis of bleeding from PHG is not recommended.<sup>113</sup>

**Nonselective β-blockers.** Nonselective β-blockers, such as propranolol and nadolol, have been shown to reduce portal pressure and gastric mucosal blood flow. In small studies, propranolol has been shown to reduce bleeding related to PHG.<sup>118,119</sup> The use of propranolol in PHG leads to endoscopic improvement, a cessation of bleeding in acutely hemorrhaging patients, and a decreased incidence of rebleeding from severe PHG. Therefore, nonselective β-blockers are a first-line therapy for secondary prophylaxis of PHG bleeding.<sup>110,121</sup> At the current time, there are not enough data to recommend β-blockers for

**FIG 18.5** Algorithm for the treatment of portal hypertensive gastropathy (PHG). APC, Argon plasma coagulation; \*NSBB, nonselective  $\beta$ -blocker; TIPS, transjugular intrahepatic portosystemic shunt.

primary prophylaxis of bleeding from PHG in patients with cirrhosis who do not require  $\beta$ -blockers for other reasons. Nonresponse to  $\beta$ -blockers, defined as continued bleeding despite this therapy and transfusion dependency despite iron-replacement therapy, should prompt consideration of interventional therapies.<sup>111</sup> Other medications, such as prednisone, estrogen, and progesterone, are ineffective for bleeding-related PHG.

**Vasoactive agents.** Given the proven beneficial effects of vasoactive agents such as somatostatin, octreotide, and terlipressin in variceal bleeding, their role in the management of PHG has also been evaluated. In patients with acute bleeding, an uncontrolled study showed efficacy with somatostatin and octreotide.<sup>122</sup> A more recent study (2001) showed that the decrease in portal pressure is only transient, however, and use of somatostatin or octreotide is unlikely to benefit patients with chronic PHG bleeding.<sup>123</sup> Use of these agents should be limited to patients with acute bleeding. There are no clinical trials directly comparing the efficacy of propranolol versus octreotide for active hemorrhage related to PHG. We recommend the use of octreotide first in patients with acute bleeding because it is better tolerated than propranolol in this setting.<sup>124</sup> The results with vasopressin and terlipressin may be inferior to that achieved with octreotide, possibly because vasopressin does not inhibit release of peptides, including glucagon and vasoactive intestinal polypeptide, and does not inhibit gastric acid secretion.<sup>125</sup> Proton pump inhibitors may indirectly stop bleeding from the stomach by raising intraluminal gastric pH and thereby stabilizing blood clots.

**Endoscopic treatment.** Endoscopic treatment does not have a significant role in the management of PHG bleeding because the bleeding is often mild and diffuse. If an active bleeding site is identified, it could be managed by injection of sclerosant or

cauterization using the heater or bipolar probe. APC or hemospray, a rapid hemostatic agent, are experimental endoscopic therapies for PHG. These therapies can treat a larger bleeding surface area than cauterization or sclerotherapy. Hemospray has recently shown promise in halting active PHG bleeding while long-term therapy is being initiated.<sup>126,127</sup> Endoscopic cryotherapy has been used for PHG bleeding after all other modalities failed.<sup>127</sup> Transjugular intrahepatic portosystemic shunt (TIPS) and shunt surgery have also been shown to be effective for PHG bleeding. A treatment algorithm for patients with PHG is described in Fig. 18.5.

### Gastric Antral Vascular Ectasia

GAVE was first described in 1984 by Jabbari and colleagues.<sup>128</sup> These authors coined *watermelon stomach* to describe GAVE because of its resemblance to the skin of a watermelon. GAVE describes vascular lesions of the antrum organized in a linear array on top of raised convoluted folds radiating outward from the pylorus, similar to spokes from a wheel, and resembling the dark stripes on the surface of a watermelon (Fig. 18.6A). The typical histologic appearance of GAVE includes marked dilation of capillaries and collecting venules in the gastric mucosa and submucosa with areas of intimal thickening characterized by fibromuscular hyperplasia, fibrohyalinosis, and thrombi.<sup>129,130,131</sup> Diffuse antral vascular ectasia or *honeycomb stomach* is recognized as the same entity as watermelon stomach, and both are regarded as GAVE (see Fig. 18.6B).<sup>132</sup>

The diffuse form is the predominant pattern in patients with cirrhosis. Noncirrhotic patients with GAVE are typically middle-aged or older women; in these patients, GAVE is associated with achlorhydria, atrophic gastritis, CREST syndrome, autoimmune

**FIG 18.6** Two different forms of gastric vascular antral ectasia: **A**, "watermelon stomach" and **B**, diffuse vascular antral ectasia.

diseases, chronic renal failure, cardiac diseases, and post–bone marrow transplantation.<sup>11,48,120,129</sup>

#### Management

Bleeding from gastric mucosal lesions in patients with portal hypertension is a serious complication, although bleeding is usually slow and insidious, and rarely massive and life threatening. However, multiple transfusions may be required during follow-up. In patients with GAVE, the reduction of portal pressure by using drugs ( $\beta$ -blockers, somatostatin, octreotide), TIPS, or surgery (portacaval shunts) are not effective. Endoscopic therapy is generally preferred because of its efficacy, but pharmacologic treatment may be used as adjunct therapy or in patients with persistent bleeding from mucosal areas not amenable to endoscopic therapy. The aim of endoscopic therapy is to eliminate completely or significantly reduce the blood transfusion requirements of a patient with bleeding.

Many studies have demonstrated the efficacy of APC; however, most have been single-center trials with a low number of subjects.<sup>130,131</sup> The tangential approach to the vascular lesions, especially along the posterior wall of the antrum, makes APC an attractive tool. Among noncontact thermal endoscopic treatments for GAVE, APC has gained popularity in recent years and is now widely available in endoscopy units. The results from several small series and case reports so far have been similar to the results achieved with the Nd:YAG laser but with a superior safety profile.<sup>132</sup> Long-term efficacy remains suboptimal, however, with a 22% incidence of recurrent bleeding and with up to 31% of patients requiring ongoing transfusions.<sup>106,133,134</sup> Long-term sequelae of ablation include antral scarring and hyperplastic polyps.<sup>135</sup> Most rebleeding episodes respond to repeated treatment, but these patients may require multiple sessions and commitment to ongoing endoscopic treatments.<sup>136</sup>

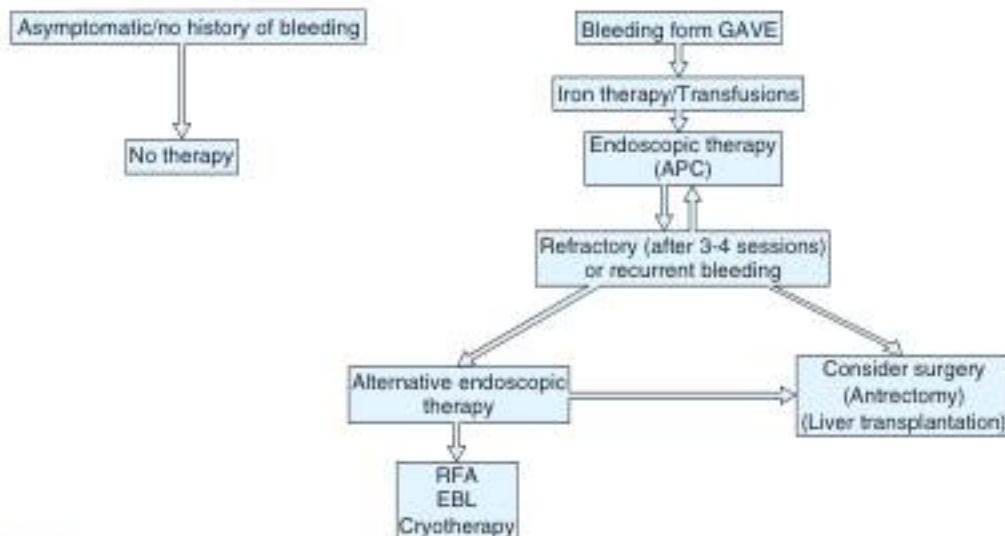

Higher power settings should be used for patients with GAVE to provide ablation of the mucosal and submucosal vascular abnormalities. Generally, a mean of 2.5 sessions are needed to achieve complete eradication, with repeated sessions every 2 to 6 weeks.<sup>136</sup> Generally, Nd:YAG laser and APC are preferred over heater probe for the treatment of GAVE because of their ability to cover a greater surface area. The endoscopic therapeutic modality chosen also depends on the individual experience of the endoscopist and local availability.<sup>134</sup> The underlying pathophysiology is unclear, and endoscopic ablative methods do not

affect the origins of the problem, so there is a long-term potential for recurrent vascular lesions and bleeding.

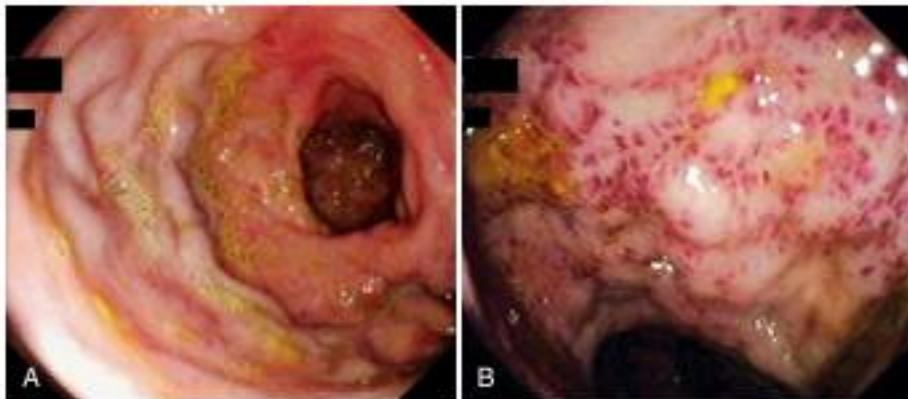

The rationale for recurrent bleeding following thermal treatment for GAVE is that GAVE commonly involves deeper structures than the superficial epithelium, including the submucosa, which may not be treated adequately with coagulation. It has been postulated that endoscopic band ligation (EBL) may more reliably obliterate vascular structures in the deep mucosa and submucosa, thus reducing the need for further treatments.<sup>130</sup> A retrospective study of thermal therapy (APC or multipolar electrocoagulation probe) compared with band ligation found that band ligation may offer a more definitive option.<sup>137</sup> Endoscopists banded vascular ectasias in the most distal antrum closest to the pylorus and then moved proximally until the entire affected areas were treated (up to 12 bands placed in a single session). Patients required between 2 and 4 sessions of EBL for resolution of GAVE. Other studies have also reported similar results.<sup>120,138,139</sup> At the present time, this form of therapy cannot be advocated as superior to existing therapies, but is an attractive option for health facilities with limited financial resources.

Cryotherapy is based on the rapid decrease of temperature due to the rapid expansion of carbon dioxide ( $\text{CO}_2$ ) released by the spray catheter; such sudden decrease of temperature causes superficial necrosis of the mucosa and of the superficial submucosal, with eradication of antral telangiectasias, and subsequent re-epithelialization. In 2003 Kantsevoy et al reported a study of 26 patients with various bleeding lesions including GAVE that were treated with cryotherapy with a mean of 3.6 sessions.<sup>130</sup> These patients had previously undergone treatment with multipolar electrocoagulation and heater probe, but continued to have bleeding. Cryotherapy was efficacious in causing hemostasis in 77% overall, with follow-up of 6 months. Preliminary data suggest that cryotherapy may be a reasonable option for diffuse GAVE lesions. Cryotherapy seems to work in GAVE by causing a deeper injury compared with APC with necrosis of mucosa and superficial submucosa, followed by re-epithelialization. A major advantage of cryotherapy over APC is its ability to treat large areas of mucosa relatively quickly because ice formation occurs after 2 to 3 seconds of spraying the mucosa and is quickly followed by thawing.<sup>135</sup>

Additional modalities that have been investigated for GAVE include radiofrequency ablation (RFA) and endoscopic mucosal resection, but are considered more investigational and cannot

**FIG 18.7** Algorithm for the treatment of gastric antral vascular ectasia (GAVE). APC, Argon plasma coagulation; EBL, endoscopic band ligation; RFA, radiofrequency ablation.

be considered as part of a more routine treatment modality.<sup>151,160,141,142</sup> A treatment algorithm for patients with GAVE is described in Fig. 18.7.

### Lesions Resembling PHG in Other Gastrointestinal Regions

Portal hypertensive gastropathy-like lesions can occur in other parts of the GI tract and are named according to the involved segment<sup>143</sup> as portal hypertensive duodenopathy, portal hypertensive biliopathy, small intestinal vasculopathy, and portal hypertensive colopathy<sup>143</sup> (Fig. 18.8). Standardized management of these lesions does not exist due to limited available data. Broadly speaking, management options are similar to those of PHG.

## HEMANGIOMAS

### Clinical Manifestations

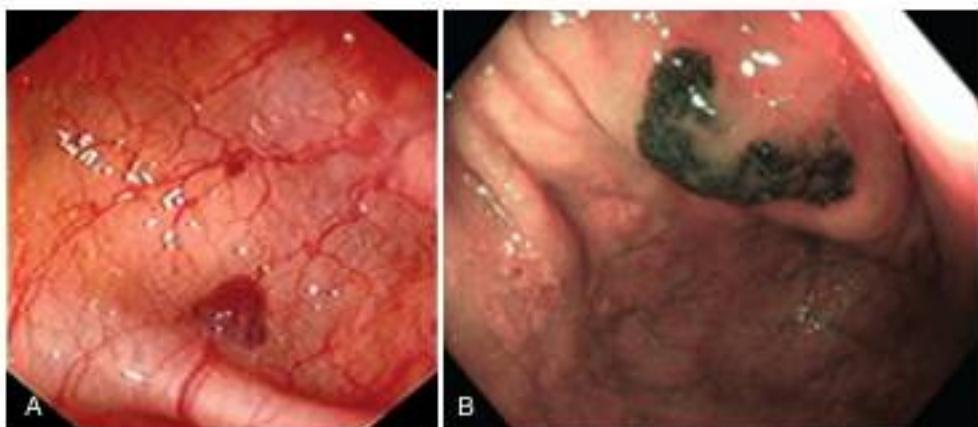

Hemangiomas are the second most common vascular lesion of the colon. They are generally thought to be hamartomas because most are present at birth. They may be solitary or multiple lesions

limited to one segment of the GI tract, or they may be part of diffuse GI or multisystem angiomyomatosis. Most are small (Fig. 18.9), ranging from a few millimeters to 2 cm, but larger lesions do occur, especially in the rectum (see later section on Cavernous Hemangioma of the Rectum). In the presence of GI bleeding, hemangiomas of the skin should suggest the possibility of associated bowel lesions.<sup>143</sup> Hemangiomas causing upper GI hemorrhage are most commonly identified in the proximal small bowel. These benign vascular tumors, almost all of which are cavernous hemangiomas, appear as single or multiple red, purple, or blue nodular lesions.

Bleeding from colonic hemangiomas is usually low in volume, producing occult blood loss with anemia or melena. Hematochezia is less common except in large, cavernous hemangiomas of the rectum, which may cause massive hemorrhage. Diagnosis is best established by endoscopy, including enteroscopy, because radiologic studies, including angiography, are frequently normal.

### Management

Hemangiomas that are small, solitary, or few in number can be treated by endoscopic coagulation using laser or other thermal

**FIG 18.9** **A**, Solitary hemangioma of the colon. **B**, Narrow-band imaging of hemangioma of the colon.

**FIG 18.10** Multiple hemangiomas of blue rubber bleb nevus syndrome. **A**, Typical dark blue nodular lesions of the skin and **B** and **C**, involving the colon.

mode. Colonoscopic excision of small lesions has been described,<sup>143</sup> including removal of small lesions for the purpose of diagnosis in patients with multiple hemangiomas.<sup>143,144</sup> Although complications of colonoscopic excision of hemangiomas seem to be rare, the number of reports is small, and it is difficult to determine the safety of colonoscopic treatment. Angiographic therapy or surgical resection may be required for large or refractory bleeding lesions.

#### Cavernous Hemangioma of the Rectum

A distinct form of colonic hemangioma is cavernous hemangioma of the rectum.<sup>145</sup> These lesions are usually not associated with other GI hemangiomas and are extensive, involving the entire rectum or portions of the rectosigmoid colon. The massive bleeding resulting from these rectal hemangiomas often necessitates excision of the rectum by either abdominal-perineal or low-anterior resection; ligation and embolization of major feeding vessels have been employed successfully. Attempts at local control have been valuable in some instances, but mostly these have been only temporarily effective.

#### BLUE RUBBER BLEB NEVUS SYNDROME

Blue rubber bleb nevus syndrome, also known as Bean's syndrome, is a rare entity, characterized by cutaneous hemangiomas and

vascular tumors of the GI tract, that can also involve other organs such as the brain, kidneys, lungs, eyes, oronasopharynx, parotids, liver, spleen, heart, pleura, peritoneum, pericardium, skeletal muscles, bladder, penis, and vulva.<sup>147–149</sup> Although a familial history is infrequent, a few cases of autosomal dominant transmission have been reported,<sup>150</sup> and one analysis identified a responsible locus on chromosome 9. The lesions were thought to be hemangiomas, but they are now considered to be venous malformations,<sup>151,152</sup> which usually appear in early childhood and tend to increase in size and number with age. They are usually blue and raised, vary from 0.1 to 5 cm in diameter, have a wrinkled surface, and are easily compressible with light palpation. The contained blood can be emptied by direct pressure, leaving a wrinkled blue sac that slowly refills over several seconds or minutes.<sup>153</sup> Skin lesions may be present throughout the body, particularly predominating on the upper limbs (Fig. 18.10A), trunk,<sup>151</sup> and face.

GI lesions are usually multiple and may involve any portion of the GI tract, but are most common in the small bowel and in the distal part of the colon.<sup>154</sup> The characteristic GI lesion is a discrete mucosal nodule with an overlying central bluish-red cap resembling a nipple, but a lesion may be a flat, macular, dark bluish-red spot or a frankly polypoid nodule with a central venous colored portion (see Fig. 18.10B and C).<sup>148,152</sup> Most patients are asymptomatic. The onset of GI bleeding may be at any time from early childhood to middle age.<sup>155</sup> The lesions can also cause

intestinal intussusception<sup>113</sup> and are associated with a variety of extraintestinal problems. Most patients respond to supportive therapy, such as iron supplementation and blood transfusion when required.<sup>132</sup> For recurrent bleeding, medical, endoscopic, and surgical therapies have been used. Medical therapy includes the use of corticosteroids,<sup>134,135</sup>  $\gamma$ -globulin,<sup>136</sup> interferon,<sup>130,135</sup> octreotide,<sup>137</sup> and sirolimus.<sup>137,138</sup>

Endoscopic management seems to be safe and useful, although the lesions can be transmural, which implies a theoretical increase in risk for bowel perforation as a complication. There are several reports of endoscopic therapy, including sclerotherapy with absolute alcohol,<sup>139</sup> sodium morrhuate,<sup>140</sup> epinephrine and polidocanol,<sup>141</sup> band ligation,<sup>141–143</sup> polypectomy,<sup>131,142,146</sup> bipolar coagulation,<sup>145</sup> and laser therapy.<sup>145,146</sup> Angiographic embolization and surgical excision have also been used.<sup>130,133,147,148</sup>

### KLIPPEL-TRÉNAUNAY-WEBER SYNDROME

Klippel-Trénaunay-Weber syndrome, also known as nevus vasculosus hypertrophicus, is a rare congenital vascular malformation, secondary to a generalized mesodermal development abnormality.<sup>150</sup> Originally described by Klippel and Trénaunay in 1900, it is characterized by bony or soft tissue hypertrophy, usually affecting one extremity (Fig. 18.11A); hemangiomas or lymphangiomas or both; and varicosities or venous malformations, appearing at birth or in childhood. Visceral hemangiomas have been described involving organs such as the GI tract (see Fig. 18.11B and C), liver, spleen, bladder, kidney, lung, and heart.<sup>144,145</sup> Involvement of the GI tract may be more common than previously believed, occurring in 20% of patients.<sup>171</sup> GI bleeding usually begins in the first decade of life and may be recurrent and mild or severe.<sup>170</sup> The severity may be enhanced by a consumption coagulopathy owing to intravascular clotting within the venous sinusoids of the hemangiomas.<sup>171</sup> The most common reported cause of GI bleeding is attributed to diffuse cavernous hemangiomas of the distal colon and rectum,<sup>172</sup> found in 1% to 12.5% of cases.<sup>170,173</sup> Less frequent causes of GI bleeding are rectal or rectovaginal varices caused by obstruction of the internal iliac system, esophageal varices secondary to prehepatic portal hypertension owing to cavernous transformation or hypoplasia of the portal vein,<sup>174</sup> and jejunal hemangiomas.<sup>175</sup> Colonic obstruction and ascites secondary to

massive hemangiomatous-lymphangiomatous retroperitoneal masses may occur.<sup>176</sup>

At colonoscopy, the rectum and the lower part of the colon may show visible mucosal vessels or compressible nodules and extensive bluish angiomatic submucosal lesions. Biopsy of the lesions should be avoided because it may precipitate severe hemorrhage.<sup>177</sup> Lesions in deeper layers of the wall can be assessed by endoscopic ultrasound.<sup>177</sup> Doppler transrectal ultrasonography could be very important for sphincter-saving surgery in patients with rectal hemangioma.<sup>178</sup> Endoscopic therapy has a limited role because of the commonly diffuse nature of the intestinal hemangiomas<sup>179</sup> and is reserved for management of localized lesions or ablation of postoperative residual disease. The use of argon<sup>180</sup> and Nd:YAG laser,<sup>179</sup> sclerosis with formaldehyde and absolute alcohol,<sup>181</sup> and placement of hemostatic clips in the rectum combined with arterial embolization<sup>182</sup> have been reported with success.

### RADIATION INJURY OF THE GASTROINTESTINAL TRACT

#### Radiation Proctopathy

##### Clinical Manifestations

Radiotherapy is a common treatment modality used for several pelvic malignancies. Despite progress in radiation techniques, adjacent organs are still exposed to chronic radiation injury, which occurs in 2% to 25% of patients.<sup>183</sup>

The rectum, a fixed organ in the pelvis, has a glandular-type epithelium in which the cells undergo a rapid turnover. This organ is particularly vulnerable to ionizing radiation and to radiation-induced complications. The incidence of such complications is proportional to the dose and its degree of spreading, and to the volume and method of irradiation (external or by brachytherapy).<sup>183</sup> Intracavitary radiation delivery has been shown to increase the risk of developing chronic radiation proctopathy (CRP).<sup>184</sup> Risk factors for radiation-induced damage include history of abdominal surgery, arteriosclerosis, obesity, diabetes, and concomitant chemotherapy.<sup>183,185,186</sup>

Radiation injury to the intestine has acute and chronic phases. Acute radiation injury occurs during or immediately after treatment and results from direct cellular damage. This injury inhibits

**FIG 18.11** Klippel-Trénaunay-Weber syndrome involving gastrointestinal tract. **A**, Hypertrophic leg caused by venous hypertension and stasis. **B**, Rectal hemangioma in the same patient. **C**, Rectal hemangiomas and venous varicosities in another patient with Klippel-Trénaunay-Weber syndrome.

**FIG 18.12** Radiation proctopathy with pale mucosa, edema, and angiectasias.

division of the intestinal crypt stem cells, and the lamina propria becomes infiltrated with inflammatory cells resulting in loss of cellular function and mucosal inflammation. Clinical symptoms of acute radiation proctitis, diarrhea and tenesmus, are usually self-resolving, requiring only symptomatic treatment and are not typically therapeutic challenges.<sup>187</sup> CRP is histologically characterized by submucosal collagen proliferation, endarteritis of arterioles, and thrombi in vessel lumens, leading to submucosal fibrosis, chronic mucosal ischemia, and progressive epithelial atrophy.<sup>188</sup> Clinical symptoms of chronic radiation usually begin months to years after the initial radiation exposure, with a median of 8 to 16 months<sup>188,189</sup> but with latencies as long as 30 years.<sup>190</sup> Symptoms include rectal bleeding, diarrhea, rectal pain, fecal urgency, tenesmus, obstructed defecation (in patients who have developed stenosis), and less commonly fecal incontinence and fistulas.<sup>187</sup> Bleeding may be severe enough to require frequent hospitalizations and blood transfusions; 55% of patients may require support with blood transfusions before undergoing definitive therapy.<sup>191</sup> Flexible sigmoidoscopy and colonoscopy aid in diagnosis and determine the extent and severity of radiation injury. The findings include distinctive angiectasias accumulated in the distal rectum, extending to and often including the dentate line, along with friability and spontaneous bleeding (Fig. 18.12). Less frequently, there may be ulceration, stenosis, and fistulas. There is often a distinct margin between normal and abnormal tissue that relates to the edge of the radiation field.<sup>191</sup> In some patients, especially women who have undergone radiation therapy after surgery for a gynecologic malignancy, there may be an associated segment of sigmoid colon with identical findings.

### Treatment

**Medical therapies.** The traditional approach to treatment of CRP has been directed toward decreasing any inflammation with the use of antiinflammatory agents such as aminosalicylic acid derivatives and corticosteroids.<sup>187</sup> The response to such agents is disappointing. Other approaches, such as promoting healing in damaged tissue with short-chain fatty acid enemas,<sup>192</sup> oral and rectal sacralfate,<sup>189,193</sup> antioxidants and vitamins,<sup>187</sup> or hormonal therapy with an estrogen-progesterone combination,<sup>194</sup> have been tried. At the moment, just a few treatments have shown, in randomized controlled trials, to be effective for the treatment of radiation-induced rectal bleeding<sup>195</sup>: metronidazole and sacralfate enemas. Small, randomized trials have shown a beneficial effect of topical rectal treatment with butyrate and

short-chain fatty acids (which exert a trophic effect on the rectal and colonic mucosa and stimulate mucosal blood flow) only for acute-onset radiation-induced bleeding but not for chronic, late-onset symptoms. The use of hyperbaric oxygen has been shown to be helpful in patients who are not controlled with endoscopic techniques. The response rate was 68%.<sup>196</sup> The response rate for bleeding was 70% to 76%; 48% showed complete resolution of bleeding, and 28% reported significantly fewer bleeding episodes.<sup>197</sup> Although this therapy is expensive and inconvenient, requiring 20 to 40 treatment sessions,<sup>186,190</sup> it could be offered to patients who fail conventional treatments.<sup>198</sup>

### Endoscopic therapies

**Topical formalin.** Topical formalin application for radiation injury was first reported in radiation-induced cystitis.<sup>201</sup> Its mechanism of action is likely to be due to a local chemical cauterization of the inflamed or fragile telangiectatic rectal mucosa.<sup>191</sup> The treatment is inexpensive and easy to perform. The technique involves the direct application of 4% formalin to the affected area in the rectum, either with formalin-soaked gauze<sup>202</sup> or by direct instillation and timed retention (typically approximately 10 minutes).<sup>203</sup> The application continues until mucosal blanching occurs, usually within 2 to 3 minutes.<sup>204</sup> The perianal area should be protected with careful draping and the application of petroleum jelly around the anus and perianal skin to avoid formalin injury.<sup>205</sup> The rectum is irrigated liberally after topical application to remove residual formalin. Formalin is contraindicated in the presence of fissures or ulceration. The short-term success of the technique with complete cessation of bleeding ranges from 59% to 100%.<sup>191,206</sup> Recurrent symptomatic relapses have been treated successfully with repeated applications.

In patients with severe CRP, the administration of topical formalin may be more effective than APC.<sup>207</sup> Complications have been described in 27% to 57% of patients.<sup>206,208</sup> According to an email survey with members of the American Society of Colon Rectal Surgeons, formalin is the most popular method to treat radiation proctitis.<sup>209</sup> However, some authors think that this technique should be reserved for severe hemorrhagic proctitis refractory to medical or endoscopic treatment, and that it should be thoroughly discussed in cases of anorectal radiation-induced stricture, prior anal incontinence, or treated anal cancer.<sup>206</sup> Formalin offers an excellent option for patients who are on anticoagulation and have increased risk for bleeding from thermally induced ulceration after conventional coagulation therapies.

**Laser.** Argon,<sup>210</sup> Nd-YAG,<sup>211</sup> and potassium titanyl phosphate (KTP) laser<sup>212</sup> have been reported to be effective, with a marked decrease in bleeding in 87% of treated patients.<sup>191</sup> Repeated treatments were needed in the long-term because symptoms tended to recur.<sup>210</sup> Laser therapy has the advantage of being a precise technique that does not involve tissue contact, is well tolerated, and improves activities of daily life. Disadvantages include its high cost, the need for protective precautions, and the risk of rectal ulcer,<sup>212</sup> bowel perforation, and rectovaginal fistulas.<sup>211</sup>

**Argon plasma coagulation.** APC is the best studied technique in the management of this disease and it is considered to be first-line therapy for CRP.<sup>213,214</sup> Nevertheless, APC settings, including gas flow rate and power, have not been standardized across publications. When the lesions are circumferential and numerous, a staged treatment may be useful, allowing a sufficient period for healing of the previously treated area. APC session intervals range from every 4 to every 8 weeks. A mean of 1.7 to 3.7 treatment sessions is necessary for control of bleeding.<sup>191</sup>

APC improves rectal bleeding in 80% to 90% of cases, as well as symptoms of tenesmus, diarrhea, and urgency in 60% to 75% of cases.<sup>214</sup> In the presence of significant oozing, adrenaline solution (1:10,000) should be sprayed over the mucosal surface,<sup>214</sup> as APC is relatively ineffective in patients with excessive bleeding owing to the absorption of current by blood on the surface. It is important to minimize contact-induced bleeding during endoscopy to maximize access to the vascular lesions. Complete anterograde bowel preparation is recommended for all treatment sessions, as good bowel preparation is crucial for endoscopic therapy.

Care must be taken not to overdistend the bowel with argon gas insufflation.<sup>215</sup> In the case of low rectal lesions, the use of a transparent cap at the tip of the colonoscope allows direct viewing of these lesions and of the upper part of the anal canal without requiring retroflexion of the endoscope. Because of its limited depth of penetration, morbidity is usually minor and consists of gas bloating, tenesmus, transient abdominal or anal pain, and diarrhea in approximately 20% of cases. Major complications are exceptional but include rectovaginal fistula,<sup>215</sup> chronic rectal ulceration, anal or rectal stricture,<sup>215</sup> and perforation.<sup>216</sup> Deliberate care should be taken to use the lowest power setting that provides a coagulum and to avoid overtreating, especially with persistent oozing after initial coagulation.

Only four studies have compared APC with other therapy for CRP.<sup>214</sup> Two compared APC with formalin, one with hyperbaric oxygen, and another study assessed APC versus bipolar circumactive probe (BiCAP). The results of these preliminary studies show that APC is at least as effective and safer than other treatments. However, more comparative studies with larger series, especially between APC and the newest techniques (radiofrequency ablation [RFA] and cryotherapy), are needed for definite conclusions.

**Endoscopic cryotherapy.** Few studies have evaluated endoscopic cryoablation as a treatment for CRP.<sup>215,216</sup> The initial case reports support the use of cryotherapy. Cryotherapy was applied every 2 to 3 days until all lesions were ablated. The average number of therapeutic sessions needed to stop the bleeding was 3.6. Cryotherapy resulted in superficial tissue necrosis that was usually completely healed within 3 months after the final treatment sessions. Cryotherapy was remarkably safe with only benign self-limited adverse events. However, there has been no prospective study comparing cryotherapy with other methods such as APC, regarding the durability of results, safety, and efficacy.

**Radiofrequency ablation.** Recently, a number of studies have evaluated the safety and efficacy of RFA for CRP treatment, the largest one including 39 consecutive cases.<sup>217</sup> RFA is generally performed on outpatients using a single-use HALO90 electrode catheter (BARRx/Covidien, Sunnyvale, CA) that is passed through a standard gastroscope. A gastroscope is used instead of a colonoscope because HALO devices are designed for a gastroscope, and because retroflexion is easier using a gastroscope, especially with the RFA catheter attached. During the ablation procedure, the HALO90 catheter is mounted in the 6 o'clock position (as opposed to the 12 o'clock location usually used for the ablation of Barrett's esophagus). To promote hemostasis, the coagulum in treated areas is not scraped off. The endoscope and device are removed for cleaning every eight applications to preserve electrode surface effectiveness for subsequent areas treatment. Ablations are performed approximately 1 mm proximal to the dentate line (to prevent sensory injury to the anal mucosa) and restricted to a short length (less than 6 cm to the dentate line).

The procedure is repeated as needed until complete rectal mucosa ablation is achieved. Based on prior studies, an energy density of 12 to 15 J/cm<sup>2</sup> at a power density of 40 W/cm<sup>2</sup> can be selected, which has shown no transmural damage at these settings.

RFA units deliver a consistent energy to the surface by using a well-defined and reproducible ramp-up of energy, thereby diminishing the likelihood of overtreatment and operator dependence that may lead to ulcerations or perforations. However,<sup>214</sup> the published studies are retrospective and conclusions are limited by the lack of a control group. They are also nonpowered, and even considering all published works, only a few dozen patients with CRP have been treated with RFA. Another important limitation is that no sigmoid or proximal rectal lesions were ablated, thus safety in those areas (with a thinner wall) remains uncertain. Therefore, additional controlled studies are required to compare RFA to other therapeutic modalities for CRP.

### Radiation Gastropathy

Gastric complications secondary to radiotherapy are uncommon, but injury can occur when the stomach lies within the radiation field of an adjacent extragastric tumor.<sup>218</sup> A high total dose, usually greater than 5000 rad, and a high daily fraction seem to be the main risk factors.<sup>218</sup> There have been reports of chronic gastroduodenal ulcerations, gastritis, and duodenitis being diagnosed days to months after selective internal radiation therapy with resin-based microspheres loaded with yttrium-90. It is possible to find small spheres located inside the vessels in the biopsy specimens.<sup>219–221</sup> Acute vasculopathy may progress to a prolonged and progressive endarteritis obliterans, vasculitis, and endothelial proliferation, leading to mucosal ischemia, ulceration, mucosal angioectasias, and fibrosis.<sup>222</sup>

In contrast to radiation proctopathy, GI bleeding from chronic radiation gastropathy is rare, with very few cases reported.<sup>223–225</sup> When present, there are multiple friable angioectasias. These lead to melena and significant blood loss requiring multiple blood transfusions, prolonged hospitalizations, and repeated endoscopies. Endoscopically, the mucosa of the affected stomach (usually antrum) is friable and with multiple angioectasias (Fig. 18.13). Other possible severe complications are perforation and gastric outlet obstruction.<sup>226</sup>

### Treatment

There is very little information in the literature on the management of radiation-induced complications in the stomach.<sup>226</sup>

**FIG 18.13** Radiation-induced gastritis with erythema, friability, and ulcerated mucosa.

**FIG 18.14** Radiation-induced duodenopathy with edema, friability, and diffuse angioectasias.

Prolonged blood loss needs to be treated with iron and folic acid supplements and with transfusions. Aminocaproic acid,<sup>225</sup> hyperbaric oxygen,<sup>226</sup> growth hormone,<sup>227</sup> and oral prednisolone<sup>227</sup> have been reported to be effective in control of bleeding in a few patients or case reports. Bleeding can be controlled by any endoscopic coagulation technique, with APC preferred<sup>225,228,229</sup> and cryotherapy.<sup>230</sup> Surgery may be necessary if other treatment fails,<sup>219,220</sup> but is associated with high morbidity.<sup>221</sup>

### Radiation Injury of the Small Bowel

The small intestine is particularly susceptible to radiation injury (Fig. 18.14).<sup>218</sup> Radiation injury to the small intestine most often occurs in the clinical setting of radiotherapy for rectal, urologic, gynecologic, or retroperitoneal malignancies. The degree of injury seems to be proportional to radiation dosage delivered to the segment of small bowel that lies within the radiation field. The relative fixed position of the duodenum and distal ileum within the abdominal cavity make these portions particularly vulnerable to radiation-induced injury. Predisposing factors in the progression of radiation injury include excessive radiation, previous abdominal surgery that fixes loops of bowel in place, underlying cardiovascular disease, and a slender build.<sup>231</sup> The mechanism of injury is vascular damage with progressive localized ischemia. The ischemia leads to angioectasias and ulceration of the mucosa, fibrosis with stricturing, and, less frequently, fistula formation or perforation.

The clinical manifestations of chronic radiation typically occur 1 to 2 years after exposure and can include malabsorption, hemorrhage, bowel obstruction, fistulas, and abscess formation secondary to perforation.<sup>232</sup> Bleeding can be managed with the same endoscopic techniques that are used in radiation proctitis. Balloon enteroscopy may be needed to access distal small bowel involvement and perform dilation of the diaphragm-like strictures, which resemble strictures seen with long-standing use of NSAIDs. The treatment is difficult, and often surgery is necessary.<sup>233</sup> Resection of the involved small bowel segment is preferable to bypass.<sup>233</sup>

### CAMERON ULCERS AND EROSIONS

Patients with large hernias may develop Cameron ulcers or erosions. These mucosal lesions are usually located on the crest of the mucosal folds that make up the distal hiatal hernia rosette, on the lesser curve of the stomach, or at the level of the

**FIG 18.15** Cameron lesions with long linear erosions (black arrows) on the crests of gastric folds in a patient with a large hiatal hernia.

diaphragmatic hiatus (Fig. 18.15).<sup>234</sup> Cameron lesions can be found in 5% of all patients with hiatal hernias.<sup>235</sup> The cause of Cameron lesions is still unclear, but it is thought that mechanical trauma secondary to diaphragmatic contraction from respiratory excursions and, perhaps, ischemia and acid mucosal injury, play a primary role in their pathogenesis.<sup>236</sup> Cameron lesions manifest clinically with chronic occult GI bleeding and associated iron deficiency anemia. These lesions can also manifest as acute upper GI bleeding in one-third of cases.<sup>231</sup> Treatment includes antisecretory therapy and supplemental iron. In approximately one-third of patients, Cameron lesions may persist or recur despite antisecretory medication, in which case surgical repair of the hiatal hernia is required.<sup>236</sup>

### INTRODUCTION

Esophageal motility disorders are ubiquitous in gastroenterology practice today, and developments in technology have led to a revolution in both their diagnosis and treatment. This chapter focuses on clinically significant esophageal motility disorders relevant to gastrointestinal endoscopy practice, primarily achalasia, but also on other potentially related disorders, including esophagogastric junction (EGJ) outflow obstruction, distal esophageal spasm, hypercontractile esophagus, and ineffective esophageal motility (IEM). For each disorder, we will review what is known regarding etiology and pathophysiology, followed by an exploration of diagnostic options available (both endoscopic and non-endoscopic) and review therapy. We will examine other potential areas in which endoscopic techniques could be employed in the management of esophageal dysmotility, including deep tissue acquisition and potentially endoscopic implantation applications. Finally, we will speculate as to what the near future may hold in the endoscopic management of these challenging conditions.

### ACHALASIA

Achalasia is characterized by loss of inhibitory neurons in the esophagus, leading to tonic contraction of the lower esophageal sphincter (LES) and altered or absent peristalsis. The term *achalasia* itself is derived from the Greek words *a* and *Khalasis*, meaning "not loosening or relaxing." The first clinical case was described by Sir Thomas Willis in 1674, where he described successfully treating a patient with associated dysphagia with a sponge-tipped whalebone, which was applied as needed after meals for approximately 15 years. The first pneumatic dilatation

was performed in 1898, and the first surgical myotomy was described in 1913 by Ernst Heller. Therapies for achalasia were relatively quiescent thereafter for much of the 20th century; however, the past 25 years have seen significant diagnostic and therapeutic advancements.

#### Etiology and Pathophysiology

Achalasia is a rare disorder with a traditionally reported incidence of approximately 1 : 100,000.<sup>1,2</sup> However, two reports from early 2017 suggest a two- to fourfold increase in incidence.<sup>3,4</sup> In the vast majority of cases, no underlying etiology is found to explain disease onset, and it is labeled as idiopathic. Achalasia can also be labeled as secondary (pseudoachalasia) if there is a defined underlying etiology leading to degeneration of the myenteric plexus due to local invasion by neoplasia or other causes, such as amyloidosis or sarcoidosis. This is relatively rare, however, and believed to account for only 2% to 4% of patients with suspected achalasia.<sup>5</sup> Chagas disease, or infection with *Trypanosoma cruzi*, is endemic in parts of South America and can also present with an indistinguishable clinical picture (at least from the esophageal standpoint). Other cases of pseudoachalasia may occur, resulting from circulating antibodies in the setting of non-local malignancy (usually small-cell lung cancer). Achalasia can also be seen rarely in certain systemic syndromes, such as Allgrove syndrome (familial adrenal insufficiency with alacrima and achalasia), Down's syndrome, and familial visceral neuropathy.<sup>3,6</sup> We will focus our discussion primarily on idiopathic achalasia, as this is by far the most commonly encountered in clinical practice.

The pathogenesis of achalasia is still unclear, but it affects the myenteric neurons that mediate and coordinate esophageal peristalsis and relaxation. The pathologic hallmark of achalasia

### Abstract

Over the past decade, significant advances have been made in the diagnosis and management of esophageal motility disorders. The advent of high-resolution esophageal manometry has allowed greater specificity in diagnosis and recognition of clinically relevant phenotypes, particularly achalasia. New diagnostic modalities including impedance and the Functional Lumen Imaging Probe have provided insight into pathophysiology and further defined disease states. Therapeutic options for achalasia continue to evolve and new seminal trials have helped clarify the pros and cons of definitive achalasia therapy, including pneumatic dilatation, Heller myotomy, and peroral endoscopic myotomy. Peroral endoscopic myotomy has gone from conception to worldwide implementation in the span of a decade and provides comparable outcomes to surgical myotomy. Emerging technology has helped define non-achalasia esophageal motility disorders, including esophagogastric junction outflow obstruction, distal esophageal spasm, and the hypercontractile esophagus. These entities are distinct from achalasia, with less defined natural history and treatment algorithms, but appear to be associated with esophageal symptoms and respond to therapy directed at underlying pathogenesis. Finally, technical advances in endoscopy have resulted in increased diagnostic and therapeutic possibilities through accessibility to the submucosal space. This chapter will summarize the diagnostic and therapeutic options for esophageal motility disorders, focusing on those with endoscopic relevance.

is a functional loss of these neurons resulting in tonic contraction of the LES and disorganized or absent peristalsis.<sup>2</sup> The trigger for this neuronal degeneration is not entirely clear, but there are data to suggest a potential autoimmune process triggered by infection in the context of genetic susceptibility.

Prior to the 1990s, the leading hypothesis with regard to pathogenesis was the degeneration of the myenteric plexus.<sup>3</sup> In the early 1990s, pathology from patients with early achalasia showed inflammatory infiltration, with subsequent studies showing T-cell predominance (in particular CD8<sup>+</sup>).<sup>4–6</sup> The question remained, however, as to what prompted this inflammation. An autoimmune hypothesis was suggested, based on evidence of circulating antibodies to myenteric neurons in patients with achalasia,<sup>7,8</sup> links to specific HLA subtypes in affected patients,<sup>11,12</sup> and the observation that patients with achalasia were also more likely to have other perceived autoimmune disorders.<sup>13</sup> However, data have not been universally supportive of this theory, as myenteric antibodies have been found to be present equally in patients with achalasia and reflux (arguing that these antibodies are not causative, but simply a marker of esophageal injury).<sup>14</sup> Arguments have also been made in favor of a potential infection. This was supported by early case reports linking achalasia to varicella, measles and polio<sup>9–11</sup>; however, subsequent detailed analyses of esophageal tissue for potential viral infection/inclusions have been negative in most affected patients, while HSV-1 has also been found in analysis of control subjects.<sup>10,20</sup> Interestingly, parrots (and over 50 other tropical birds) suffer from proventricular dilatation disease, which is histopathologically indistinguishable from achalasia, but in contrast to human disease, it occurs in outbreaks. Recently, avian bornavirus was identified as the cause,<sup>21</sup> but it does not have any human equivalent. At present, most authorities subscribe to a combination of the aforementioned theories, that prior viral infection triggers immune-mediated ganglionitis, resulting in loss of myenteric neurons in a genetically-susceptible host.

### Clinical Manifestations

The most common symptoms of achalasia are dysphagia and regurgitation. Dysphagia occurs with both solids and liquids, and is seen in over 90% of patients. Of note, a proportion of patients will not have dysphagia in both consistencies, and a distinct minority (< 5%) will not report dysphagia at all. Regurgitation of undigested foods is reported in 59% to 91% of patients and may be the dominant symptom at presentation. Chest pain occurs to a variable degree (17%–64%) and is more pronounced in spastic variants and perhaps in younger patients. Patients may also report heartburn (18%–75%), which, although counterintuitive, is likely related to stasis of ingested contents or intraesophageal reflux. Weight loss and aspiration are more worrisome but fortunately are seen less frequently (10%–30%).<sup>1,2</sup>

Symptoms associated with achalasia can be non-specific and the diagnosis is often not straightforward. Dysphagia is reported in approximately 4% of American adults on a weekly basis<sup>22</sup> and achalasia has an incidence of approximately 1:100,000,<sup>23</sup> so, not surprisingly, the vast majority of patients who present with dysphagia will not have achalasia, nor is it at the top of the differential diagnosis given its relatively rarity. Dysphagia is not seen in all patients with achalasia, and the presence of heartburn and chest pain can often sway presumptive management toward more common entities, such as gastroesophageal acid reflux. Despite the colloquial association of achalasia with weight loss, it is not unusual to see obese patients with achalasia. At tertiary

facilities, a small percentage (< 3%) of patients referred for evaluation of refractory reflux will eventually be diagnosed with achalasia. Because of these factors, many series report a relatively long delay (up to 5 years) between symptom onset and establishment of a final diagnosis.<sup>13,24</sup> With regard to other key demographics, men and women are affected evenly, and there is no reported gender discrepancy. Achalasia has increasing incidence with age, with an estimated incidence of greater than 10:100,000 above 80 years of age and less than 1:100,000 below 16 years of age; however, it can be reported at any age, and in our practice we have seen patients diagnosed at both younger than 1 year of age and older than 90 years.

### Diagnosis

Accurate diagnosis of achalasia depends on recognition of associated symptoms and careful employment of diagnostic modalities to identify the underlying etiology and exclude mimicking conditions. For those patients who present with dysphagia, the key first step is to exclude a mechanical or infiltrative process using endoscopy or barium esophagography. Due to improvement in endoscopic technology and the clinical emergence of eosinophilic esophagitis, endoscopy is often the first-line study employed for evaluation of dysphagia in community and academic practices; however, there are no guidelines that specifically recommend endoscopy over a barium esophagography in the initial evaluation of dysphagia, and either approach would be reasonable, based on local practice patterns and expertise.

### Endoscopy

Patients presenting with dysphagia and suspicion for achalasia should undergo endoscopy for evaluation and exclusion of potential neoplasms masquerading as pseudoachalasia. Esophageal biopsies to exclude eosinophilic esophagitis or other infiltrative disorders should be performed. In many patients with achalasia, especially early cases without significant esophageal dilatation, the endoscopy is unremarkable. Subtle endoscopic findings include frothy secretions in the esophagus and subjective feeling of tightness to the passage of the endoscope at the EGJ. In more advanced cases, esophageal distention, tortuosity, retention of pooled liquid or food, or frank food impaction can be seen; however, these are usually later findings denoting advanced disease. Due to stasis, it is also not unusual to see associated Candidiasis and, in the absence of immunosuppression, this finding on endoscopy should raise warning with regards to potentially significant dysmotility (Fig. 19.1). Endoscopy cannot definitively establish the diagnosis of achalasia and additional evaluation is required.

### Radiology

A barium esophagram allows objective assessment of esophageal emptying, diameter, and contour, and can provide information relative to structural abnormalities, including epiphrenic diverticula, that may not be appreciated on endoscopy. In early cases or cases not associated with esophageal dilatation, it is important to recognize that the barium study may be interpreted as normal, and in fact some series report that almost half of early achalasia cases may be missed if relying on barium study alone.<sup>25,26</sup> However, although not sensitive, esophageal fluoroscopy can be quite specific in advanced cases. Characteristic findings include a dilated esophagus with retained food or an air-fluid level, and narrowing at the EGJ, often referred to as a *bird-beak*. Other findings seen in advanced cases include a large intragastric air bubble and

**FIG 19.1** Examples of the possible endoscopic appearance of a spectrum of patients with achalasia.

**A.** A subjectively tight esophagogastric junction is visualized, which, albeit subtle, may be an early marker of diagnosis. **B.** A spastic esophagus is visualized, typical of what is occasionally seen with type III (spastic) achalasia. **C.** A dilated atonic esophagus is seen with stasis and retained food, which is a more specific finding and generally associated with more chronic disease. **D.** An end-stage esophagus is seen with massive dilatation and characteristic mucosal change.

severe esophageal dilatation with a sigmoid-like appearance (Fig. 19.2). A timed barium esophagram can also be employed, where the patient ingests a fixed amount of barium and then retention is measured at 5 minutes while the patient is upright. This allows objective assessment of functional esophageal emptying and can be followed longitudinally after therapy.

Esophageal fluoroscopy remains an invaluable part of the diagnostic evaluation due to its unique ability to visualize anatomy and diameter. It is our practice to always obtain a barium esophagram before proceeding with more invasive treatment options in a patient with suspected achalasia.

In select cases, one could also consider other imaging modalities, including computed tomography (CT). CT scans in achalasia had characteristic findings highlighted by esophageal dilatation with normal wall thickness; however, patients with suspected achalasia who were found to have secondary achalasia had atypical radiographic manifestations.<sup>27</sup> CT is useful in separating primary

and secondary achalasia, with nodular/lobulated or asymmetric distal wall thickening, mediastinal lymphadenopathy, or a soft-tissue mass being supportive of a secondary process.<sup>28</sup> We do not routinely obtain cross-sectional imaging on all patients with achalasia; however, for complicated cases or patients with atypical features there may be a role.

### Manometry

Esophageal manometry is considered the gold standard for the diagnosis of achalasia and has the highest sensitivity for detection of early disease. The past decade has seen the emergence of high-resolution esophageal manometry (HRM) with esophageal pressure topography, which is now the standard of care in most institutions. The concept of HRM stems from Clouse (1998)<sup>29a</sup> at Washington University, who speculated that, by increasing the number of monitoring channels and decreasing the distance between those channels, diagnostic yield would be

**FIG 19.2** Examples of the possible radiographic appearance of a spectrum of patients with achalasia. **A**, The esophageal diameter appears relatively normal and an air-fluid level or significant esophagogastric junction (EGJ) narrowing is not appreciated. As sensitivity of fluoroscopy for detection of achalasia is significantly lower than manometry in early disease, this is not an unusual finding in patients with early disease. **B**, A dilated esophagus is seen with an air-fluid level and narrowing at the EGJ consistent with a classic "bird-beak" appearance. **C**, A mega-esophagus with sigmoidization is shown on chest computed tomography. Unfortunately, in the context of an end-stage esophagus, therapies directed at amelioration of lower esophageal sphincter pressure alone may not be effective and esophagectomy is often required.

**TABLE 19.1 The Chicago Classification for Esophageal Motility Disorders**

Diagnosis	HRM Chicago Classification (v.3) Criteria
<b>Disorders of Outflow Obstruction</b>	
Achalasia	
Type I	Elevated median IRP with 100% failed peristalsis
Type II	Elevated median IRP with 100% failed peristalsis and intermittent pan-esophageal pressurization ( $\geq 20\%$ swallows)
Type III	Elevated median IRP; premature (spastic) contractions ( $\geq 20\%$ swallows), no normal peristalsis
EGJ outflow obstruction	Elevated median IRP with preserved peristalsis (not meeting criteria for achalasia)
Major motility disorders	
Absent contractility	Never encountered in healthy subjects
Distal esophageal spasm	Normal median IRP with 100% failed peristalsis
Hypercontractile esophagus (jackhammer esophagus)	Normal median IRP; premature (spastic) contractions ( $\geq 20\%$ swallows)
Hypercontractile esophagus (jackhammer esophagus)	
Hypercontractile esophagus (jackhammer esophagus)	Hypercontractile esophagus with DCI > 8000 mm Hg/s per cm ( $\geq 20\%$ swallows)
Minor motility disorders	
Ineffective esophageal motility	Seen in some healthy asymptomatic controls and of uncertain clinical significance Intermittent weak or failed contractions ( $\geq 50\%$ swallows) with periodic normal peristalsis (DCI > 450 mm Hg/s per cm)
Fragmented peristalsis	$\geq 50\%$ fragmented contractions with normal DCI (> 450 mm Hg/s per cm)
Normal	Not meeting any of the previous criteria

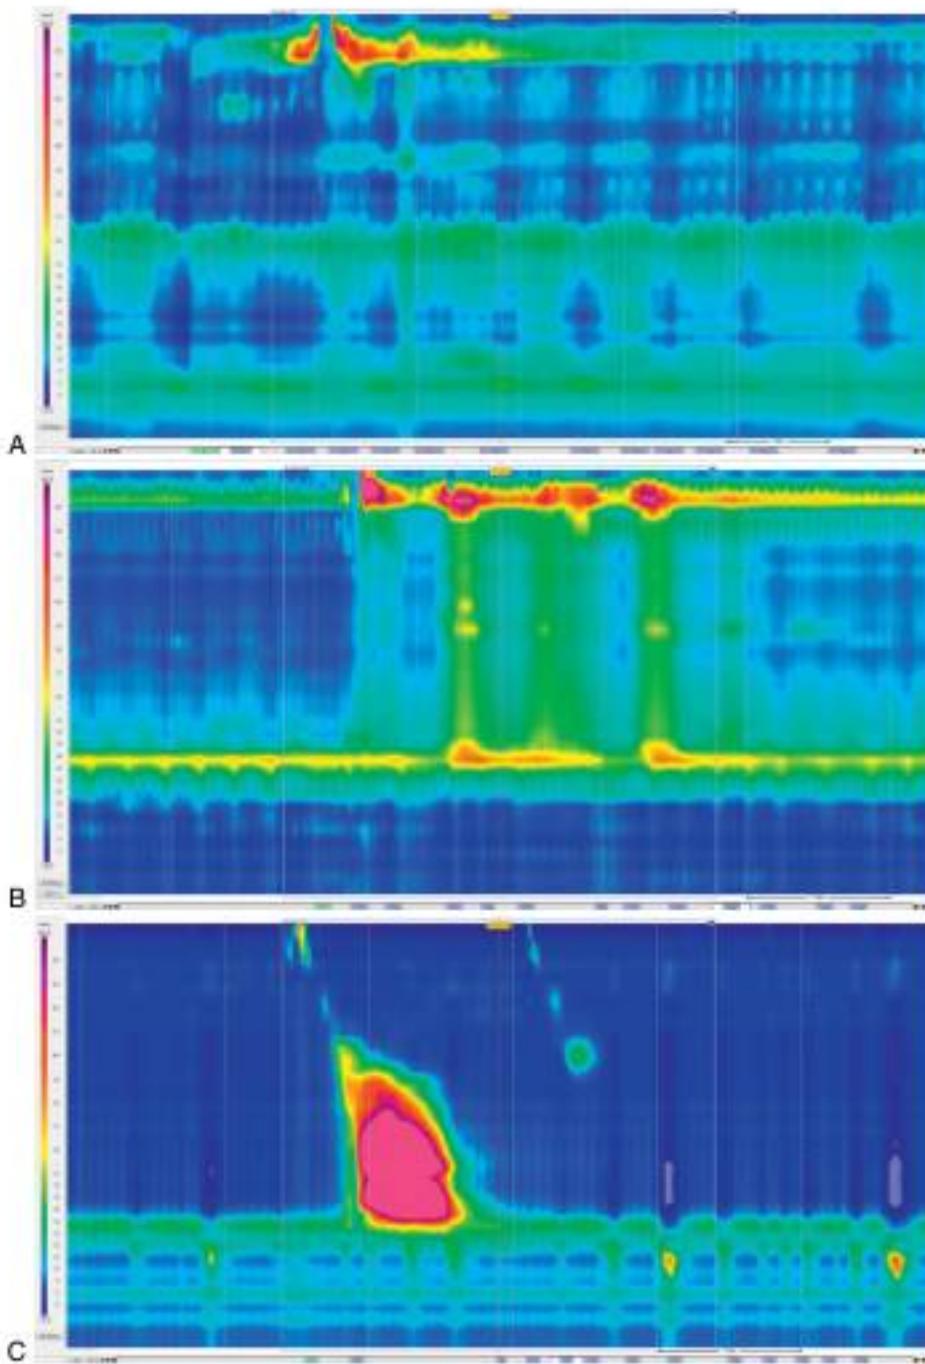

DCI, Distal contractile integral; EGJ, esophagogastric junction; HRM, high-resolution esophageal manometry; IRP, integrative relaxation pressure.

Adapted from Kahrilas PJ, Bredenoord AJ, Fox M, et al: The Chicago Classification of esophageal motility disorders, v3.0. *Neurogastroenterol Motil* 27(2):160–174, 2015.

enhanced. Pinnacle work in HRM was performed by investigators in Europe and at Northwestern University in the early 2000s, and their combined work eventually led to the Chicago Classification for Esophageal Motility Disorders, widely considered the core reference for esophageal manometry interpretation today and currently on its third rendition (Table 19.1).<sup>29–31</sup>

When interpreting HRM using the Chicago Classification, the diagnosis of achalasia relies on the identification of impaired LES relaxation (as defined by an elevated integrative relaxation pressure [IRP]) in tandem with identification of absent or aberrant peristalsis. One of the key advantages to HRM has been the ability to recognize clinically meaningful achalasia subtypes that

predict clinical course and response to therapy. In 2008, Pandolfino and colleagues at Northwestern University described three distinct manometric achalasia subtypes (types I, II, and III) (Fig. 19.3). In all three, there was abnormal relaxation of the LES/EGJ, defined by an elevated IRP. In type I achalasia, the esophageal body displayed absent peristalsis. In type II, the esophageal body displayed simultaneous, pan-esophageal pressurization with wet swallows. In type III, the esophageal body displayed (for at least some swallows) disorganized contractility akin to spasm. These investigators showed that outcomes to therapeutic intervention varied depending on manometric subtype and, specifically, that patients with a type II pattern (characterized by pan-esophageal

**FIG 19.3** Examples of the three high-resolution esophageal manometry (HRM) achalasia subtypes. **A**, Type I (or classic) achalasia is characterized by impaired esophagogastric junction (EGJ) relaxation with absent contractility in the esophageal body. **B**, Type II achalasia is characterized by impaired EGJ relaxation in tandem with pan-esophageal pressurization in the esophageal body. This is the phenotype with the best prognostic implications. **C**, Type III (or spastic) achalasia is characterized by impaired EGJ relaxation with evidence of rapid distal latency/spasm in at least 20% of wet swallows.

pressurization) had excellent outcomes to therapy, whereas patients with a type I pattern required more definitive sphincter disruption and patients with a type III pattern did not respond as well to intervention aimed solely at the LES.<sup>52</sup> This work has now been replicated by others, confirming robust therapeutic response for those with type II achalasia.

The sensitivity of manometry is, however, imperfect, and there are cases that fall outside conventional diagnostic paradigms.<sup>53</sup> The Chicago Classification relies on the IRP as a marker of degllutitive EGJ relaxation; however, there are some patients with achalasia who may have true sphincteric dysfunction with a technically normal IRP. In cases where the manometry is not

classic but clinical suspicion for achalasia is high, other complementary tests (such as barium or the Functional Lumen Imaging Probe [FLIP; Crospon, Galway, Ireland]) will need to be employed. Likewise, there are patients who have manometric impairment of deglutitive relaxation but preservation of peristalsis. These patients are currently defined by the Chicago Classification as having EGJ outflow obstruction, a diagnosis of uncertain clinical significance, that in fact could be an achalasia variant or achalasia in transition.<sup>24</sup> Although HRM is considered the most sensitive test for recognition of early achalasia, it is not perfect and there will be some patients (albeit rarely) who clinically have achalasia but may not meet current manometric definitions.

### Impedance

Impedance refers to opposition to current within a closed circuit and, when applied to esophageal physiology, it can measure movement of bolus (air, liquid, or food) throughout the esophageal body. Achalasia is characterized by aberrant bolus transit, which can be measured directly via impedance. This was first demonstrated elegantly by Castell and colleagues from Medical University of South Carolina in 2004.<sup>25</sup> However, impedance measurements alone do not distinguish achalasia from other conditions, such as scleroderma, which also result in impaired bolus transit. Likewise, some patients with type III achalasia on HRM may have relative preservation of bolus transit despite a clear manometric diagnosis. For these reasons, impedance serves only a complementary role at present in the diagnosis of achalasia.

There have been two developments with regard to impedance, however, which are worth mention. To begin with, investigators from Northwestern (2014) have evaluated bolus clearance via impedance in comparison to the traditional timed barium swallow.<sup>26</sup> The hypothesis is that monitoring bolus clearance via impedance in conjunction with manometry would be technically simple and may provide similar information regarding functional emptying of the esophagus to that of the timed barium swallow, but would obviate the requirement for radiation and perhaps be more acceptable as a long-term option. Initial data appear promising; however, it should be noted that timed impedance monitoring will only assess functional emptying of the esophagus and will not provide the same information regarding esophageal diameter and anatomy that is provided via fluoroscopy. Whether that gain is worth periodic radiation exposure, however, remains uncertain. The second key development with impedance relates to the use of mucosal impedance as a diagnostic marker for esophageal mucosal integrity. This has been found to be abnormal in esophageal disease states, including achalasia; however, it is not specific enough to reliably separate achalasia from other entities that may impact mucosal integrity and at present remains only a complementary test.<sup>27</sup>

### Functional Lumen Imaging Probe

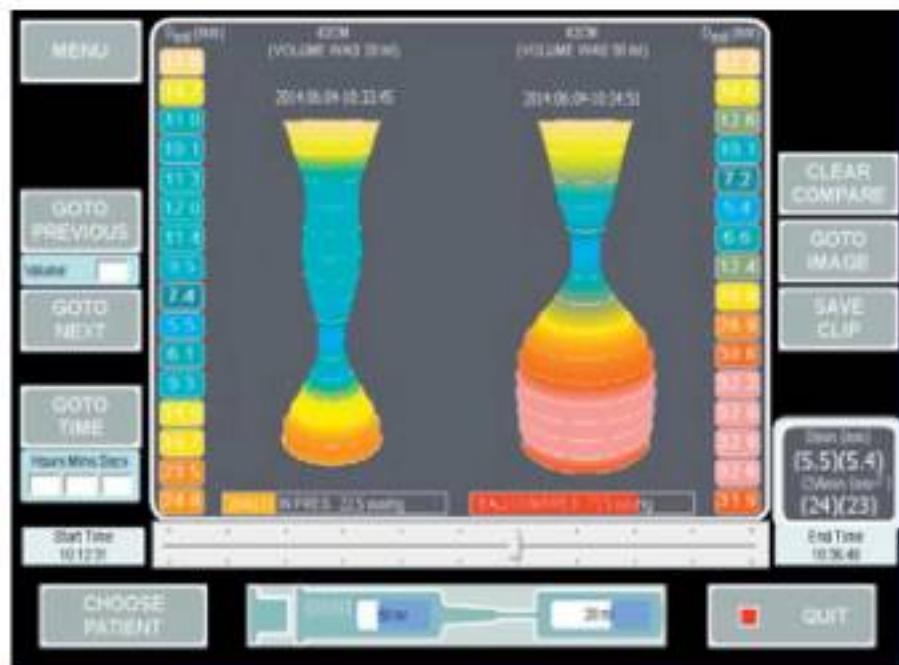

Clinical characterization of esophageal motility disorders has become increasingly multimodal and existing technologies rely primarily on assessment of pressure patterns or bolus flow; however, biomechanical properties of the esophageal wall are likely also an important component in many patients. FLIP has proved to be a novel key addition. The concept of FLIP is based on the use of impedance measurements within a fluid-filled, high-compliance balloon. By knowing the volume of fluid instilled in the balloon and the conductance of that fluid, it is possible to determine the diameter of the balloon between each set of impedance rings; when combined with a pressure sensor, the

distensibility of the lumen can be calculated. Development of the device was based on the work of Gregersen in the early 1990s, leading to its commercialization and eventual approval in the United States and Europe.<sup>28,29</sup>

FLIP offers a unique vantage point for the evaluation of patients with potential achalasia, in that it allows direct measurement of EGJ distensibility and diameter. Not surprisingly, research has suggested that distensibility at the EGJ is decreased in the setting of achalasia and reliably improves after mechanical therapy. This was initially demonstrated elegantly in a study of 30 patients with achalasia and 15 healthy controls, showing a marked difference in distensibility between patients with untreated achalasia (distensibility index [DI]:  $0.7 \pm 0.9 \text{ mm}^2/\text{mm Hg}$ ) and healthy controls (DI:  $6.3 \pm 0.7 \text{ mm}^2/\text{mm Hg}$ ); moreover, changes in distensibility after therapy predicted clinical response, with patients with good clinical outcome showing increased distensibility (DI:  $4.4 \pm 0.5 \text{ mm}^2/\text{mm Hg}$ ) compared with those who had unsuccessful treatment (DI:  $1.6 \pm 0.3 \text{ mm}^2/\text{mm Hg}$ ). Of interest, over half the patients with persistent symptoms after achalasia therapy were noted to have an adequate posttherapy manometry, suggesting that the FLIP measurements provided additive benefit over traditional means of assessment.<sup>30</sup> In a subsequent analysis of 54 achalasia patients and 20 healthy controls, investigators from Northwestern University reported very similar findings, noting a gradient of distensibility between untreated achalasia ( $0.7\text{--}1.1 \text{ mm}^2/\text{mm Hg}$ ), treated achalasia with poor response ( $1.1\text{--}1.5 \text{ mm}^2/\text{mm Hg}$ ), treated achalasia with good response ( $1.8\text{--}3.5 \text{ mm}^2/\text{mm Hg}$ ), and healthy controls ( $4.2\text{--}8.2 \text{ mm}^2/\text{mm Hg}$ ).<sup>31</sup> A 2017 study from investigators in Amsterdam (The Netherlands) has raised the question of whether FLIP may in fact be a more sensitive test for the detection of achalasia than manometry.<sup>32</sup> In our practice, FLIP is an important complementary test to evaluate those patients with symptoms suggestive of achalasia, but conflicting data from other diagnostic modalities or, more frequently, as a means to assess sphincter dynamics in the context of ongoing symptoms after treatment. A clinical example highlighting the use of FLIP in the evaluation of a patient with achalasia is shown in Fig. 19.4.

A key recent development with regard to FLIP has been the formulation of FLIP topography and incorporation of this modality in the evaluation of dysphagia. This has been championed by the Northwestern Group, who have compared FLIP topography to HRM. In their patients with dysphagia (approximately half of whom had achalasia by manometry), FLIP topography showed aberrant contractility patterns in 95% of patients with a major motility disorder characterized by HRM, but also provided additional information in 50% of patients with significant clinical symptoms and an unremarkable HRM.<sup>33,34</sup> At present, data regarding FLIP topography remain limited to a few academic centers; however, with commercialization, this modality is expected to be much more widely available in the near future.

The final role of FLIP in the evaluation of patients with suspected achalasia, patients with established achalasia and symptoms despite therapy, and in the intra-procedural tailoring of achalasia therapy remains to be determined; however, the published data look promising, and the ability to measure EGJ distensibility and diameter directly are compelling arguments for future use and development. Moreover, this test has the capability of being performed during endoscopy, which is invariably already being performed for these patients, rather than as a separate standalone procedure, such as manometry. Where

**FIG 19.4** A Functional Lumen Imaging Probe (FLIP) study performed on a patient referred for evaluation of persistent dysphagia. Achalasia was clinically suspected, but prior endoscopy, barium esophagram, and several manometry studies had not confirmed the diagnosis. The FLIP procedure was performed and the figure shown is with the balloon placed across the esophagogastric junction. The image on the left represents the balloon with 20 cc of fluid instilled, whereas the image on the right represents the balloon with 30 cc of fluid instilled. With increased fluid, there was minimal change in diameter and cross-sectional area, but pressure markedly increased. The distensibility index for this patient was 0.3. This study confirmed a diagnosis of achalasia and the patient was treated with peroral endoscopic myotomy (POEM) with excellent clinical results.

FLIP ultimately is placed in the diagnostic algorithm for achalasia remains to be determined; however, it clearly will have a role.

### Therapy

The physiologic hallmarks of achalasia are impaired LES relaxation and absent or aberrant esophageal peristalsis. As achalasia is a chronic degenerative condition, there is no cure per se; however, most patients will respond effectively to therapy aimed at disruption of the LES and effective removal of the esophageal outlet barrier. Current treatment options include observation, medical therapy, botulinum toxin injection, pneumatic dilatation, Heller myotomy with or without partial fundoplication, peroral endoscopic myotomy (POEM), stent placement, and esophagectomy. Observation is generally viewed as a poor option because untreated achalasia can lead to progressive esophageal dilatation with aspiration, less robust response to the aforementioned therapies, and potentially the need for esophagectomy. For this reason, early treatment is recommended once the diagnosis is established, both to improve symptoms and to prevent progression to an end-stage mega-esophagus.

### Medical Therapy

Medical therapy for achalasia is of limited utility. Three classes of agents have been studied: calcium channel blockers,<sup>13–16</sup> nitrates,<sup>15,17–19</sup> and phosphodiesterase inhibitors.<sup>20</sup> The hypothesis is that smooth muscle relaxation will reduce LES pressure, reduce esophageal contractility if spastic achalasia is present, and assist in esophageal emptying. Nifedipine, given in sublingual doses

of 10–20 mg prior to meals, is the most widely used medical agent and can decrease LES pressure by 30% to 60% with modest improvement in dysphagia; however, side effects associated with hypotension (headache, dizziness) are significant. Furthermore, there are no data to suggest that medical therapy in any way changes the natural history of achalasia. Moreover, the temporal effects of this therapy on LES dynamics are relatively brief. Tachyphylaxis is noted, and even the marginal initial benefit observed often reaches a plateau after which drug efficacy wanes. In addition, absorption of these medications can be difficult to predict in the context of significant achalasia and delayed esophageal emptying, further compounding the issue. Phosphodiesterase inhibitors may offer similar benefits without as much hypotension as nitrates and calcium channel blockers; however, data are limited. All published series represent short-term use, and there are no long-term trials available to support efficacy of this approach. In our practice, medical therapy for achalasia is employed solely as a bridge to more definitive therapy directed at sphincter disruption.

### Botulinum Toxin

The use of botulinum toxin injection of the EGJ for treatment of achalasia was first proposed by Pasricha et al at Johns Hopkins in 1994. Botulinum toxin A is a neurotoxin that blocks the release of acetylcholine from excitatory nerve terminals, leading to decreased muscle contraction and effective reduction in LES pressure. After promising animal experiments, a pilot study was conducted in patients with achalasia and revealed short-term

success.<sup>51</sup> This led to a double-blind, placebo-controlled trial wherein 90% of patients with achalasia treated with botulinum toxin reported improvement at 1 week, with approximately two-thirds still reporting improvement at 6 months.<sup>52</sup> However, the effect is temporary and eventually reversed with axonal regeneration. Duration of benefit is typically approximately 9 months, although individual patients may report shorter or longer duration of benefit. Published data suggest decreased efficacy with repeated injection, and fibrosis can be seen with repeated injections, potentially worsening future surgical outcomes.<sup>53</sup>

The initial publications by Pasricha and colleagues employed a dose of 80 units, divided in a circular fashion and injected under endoscopic visualization into the presumed LES. As botulinum toxin is dispensed typically in 100-unit vials, most subsequent publications have utilized this dose. The conventional approach is to mix the botulinum toxin in 4 cc of saline and then inject 1 cc in four quadrants approximately 1 cm proximally to the z-line under endoscopic visualization. Higher doses of botulinum toxin have not been shown to be more effective for treatment of achalasia.<sup>54</sup> Some centers have proposed use of endoscopic ultrasound to aid in placement of the neurotoxin in the LES directly, rather than blind endoscopic injection<sup>55</sup>; however, there are no randomized trials to show that this results in superior outcomes, and in our practice endoscopic ultrasound is not employed for this procedure.

Because of the short duration of benefit, the question of injection-related fibrosis potentially complicating future therapies, and decreased efficacy with time, botulinum toxin is not generally viewed as an ideal first-line therapy for most patients with newly diagnosed achalasia. However, it can be an excellent option for some patients. In our practice, we often employ botulinum toxin in four distinct patient subgroups: (a) those who are either elderly or generally too frail to undergo more definitive therapy (pneumatic dilatation, surgical myotomy, or POEM). Botulinum toxin has a generally good safety profile and in the short-term is a safer option than the other more invasive definitive therapies; (b) those in whom the diagnosis remains in question despite appropriate testing. Between endoscopy, fluoroscopy, manometry, impedance, and FLIP there are multiple means by which esophageal motility can be interrogated and it is not rare that the results of the diagnostic evaluation are incongruent, with some studies suggestive of achalasia and others arguing against. In this situation, we often employ botulinum toxin as a diagnostic test, with the hypothesis that the safety profile is good and if they have significant clinical improvement, they would be amenable to more invasive definitive therapies; (c) those with recurrent symptoms after achalasia therapy, where the pertinent question is whether their symptoms stem from continued sphincteric impairment versus a combination of hyperawareness, hypersensitivity, and aperistalsis. We find this particularly useful for patients who have had a prior Heller myotomy or POEM but may have a short residual remnant sphincter; (d) those patients with predominant chest pain and evidence of spasm. Given that chest pain may not respond as well to mechanical disruption of the LES, we may try botulinum toxin in that subgroup specifically. For most patients with achalasia, however, we do not recommend botulinum toxin as the first-line therapy for the reasons detailed previously.

### Pneumatic Dilatation

The concept behind pneumatic balloon dilation is to partially tear the LES by forceful balloon expansion, usually, although

not always, utilizing air. Early literature with pneumatic dilatation quoted high perforation rates (> 5%); however, with adoption of the newer Rigiflex balloons (Boston Scientific, Marlborough, MA), those rates are decidedly lower. In a systematic review of 24 studies encompassing 1144 patients with an average follow-up of approximately 3 years, the overall clinical response to pneumatic dilatation was 78%; however, there was a graded response rate based on the balloon size employed. Dilatation using a 3.0-cm balloon alone resulted in a clinical improvement rate of 74%, versus 86% with a 3.5-cm balloon and 90% with a 4.0-cm balloon. Approximately one-third of patients were noted to have recurrence of symptoms requiring additional intervention, usually a repeat pneumatic dilatation. The perforation rate was 1.9%.<sup>56,57</sup> Predictors of decreased response include age over 40 years, male gender, dilated esophagus, small-size balloon, a single dilatation procedure, LES pressure greater than 10 to 15 mm Hg within a year of the procedure, poor esophageal emptying via barium swallow following treatment, and a type III HRM pattern.<sup>1</sup>

Since this series, two large, multicenter trials have provided additional information. The European Achalasia Trial compared pneumatic dilatation versus laparoscopic Heller myotomy for idiopathic achalasia in 201 patients. In the initial protocol, a 35-mm balloon was employed for the first dilatation; however, perforation occurred in 4 of the first 13 patients, and the protocol was subsequently changed so that all patients started with a 30-mm balloon. All patients included in the trial analysis underwent dilatation using a 30-mm balloon followed by dilatation using a 35-mm balloon 1 to 3 weeks later. If they were still symptomatic thereafter (defined by an Eckardt score > 3), then they underwent a subsequent third pneumatic dilatation using a 40-mm balloon. Using this protocol, the investigators achieved a 90% 1-year success rate, 86% 2-year success rate, and 82% 5-year success rate, all of which were statistically similar to those achieved via laparoscopic Heller myotomy.<sup>58,59</sup> However, the rate of perforation for pneumatic dilatation was higher than typically reported in the achalasia series (4.1%), even after discounting the initial four perforations utilizing a 35-mm balloon alone. Recently, a large multicenter study evaluating POEM versus pneumatic dilatation for treatment of therapy-naïve achalasia was presented. In this protocol, all patients randomized to pneumatic dilatation underwent initial dilatation utilizing a 30-mm balloon and then subsequently underwent dilatation utilizing a 35-mm balloon if they remained symptomatic (defined by an Eckardt score > 3) or had evidence of stasis on barium esophagram. Utilizing this less aggressive protocol, 1-year success was reported in 78.8% of patients, with a perforation rate of 1.5%.<sup>60</sup> Putting this information together with prior reports, one can surmise a response rate with pneumatic dilatation of approximately 70% to 80% with an estimated rate of perforation of less than 2% if a conservative approach is employed, starting with a 30-mm balloon and then increasing to a 35-mm balloon if the patient remains symptomatic or has objective evidence of continued impairment in emptying. If one is willing to employ a more aggressive approach (as was done in the European Achalasia Trial), then success rates will be higher (approaching 90% at 1 year), but with the trade-off of an increased perforation risk. Regardless of the approach taken, it is important to recognize that success will wane with time and patients may require additional intervention, usually with a repeat dilatation.

Pneumatic dilatation is typically performed in the endoscopy suite utilizing fluoroscopic guidance. If the risk of aspiration is significant (e.g., if the patient has food or liquid retention on

prior endoscopy or imaging), then a liquid diet may be employed for a few days and a longer preprocedure fasting period may be utilized. Efforts should be made to perform these procedures in the morning, as patients may require extended postprocedure monitoring. Either conscious sedation in the left lateral position or anesthesia with airway protection can be employed, based on aspiration risk and local practice patterns. During endoscopy, a Savary guidewire is placed in the stomach under endoscopic guidance, and the endoscope is subsequently removed. A Rigiflex balloon (Boston Scientific) is then passed over the guidewire and fluoroscopically positioned across the narrowed EGJ region. The balloon is then inflated until the radiographic waist from the LES (located ideally in the middle of the balloon) is flattened. If utilizing air, the pressure needed is typically 7 to 15 psi. The balloon can be held in place for 60 seconds if desired, although there is no convincing evidence that keeping the balloon inflated longer than what is required to achieve initial waist flattening improves outcomes. The balloon is then deflated and removed. In some centers, radiographic contrast may be used instead of air to enhance radiographic visualization. The patient is then typically monitored for 2 to 6 hours postprocedure. A gastrografin esophagram can be employed to evaluate for perforation if there is significant pain. Some centers obtain this routinely after pneumatic dilatation to exclude perforation, but this is controversial, and in our practice formal radiographic studies are only obtained postprocedure if there are symptoms that suggest a possible complication. Clinical response should be seen within 1 week following the procedure, although there is some patient heterogeneity. Some centers have published on pneumatic dilatation without fluoroscopy; however, we believe fluoroscopy aids in optimal balloon placement, and we always utilize it. Of note, a 30-mm dilator has been recently released using the FLIP system. Data regarding this dilator are limited, but utilization of this balloon may potentially obviate the need for fluoroscopy.

### Heller Myotomy

The idea behind surgical myotomy is to identify the impaired muscle region and to cut the LES and adjacent regions, affecting both the longitudinal and circular fibers, such that the mechanical obstruction is eliminated. The first minimally invasive approach to achalasia was reported by Pellegrini in 1992 using thoracoscopy; however, a laparoscopic approach has since become the standard of care. A systematic review of data from over 3000 laparoscopic Heller myotomies reported an overall clinical success rate of approximately 90%.<sup>62</sup> More recently, Boeckxstaens et al (2014) reviewed all laparoscopic myotomy series with a sample size of more than 100 patients. In their review of 2264 patients with a mean follow-up of 42 months, clinical efficacy was reported to be 84%.<sup>1</sup> This is in line with the recent 5-year data from the European Achalasia Trial, which also reported a 5-year clinical success rate of 84% in their series of 105 patients who underwent laparoscopic Heller myotomy.<sup>59</sup> Laparoscopic Heller myotomy is clearly superior to pneumatic dilatation if a single balloon dilatation session is employed, but the European Achalasia Trial suggests that the two approaches are equivalent if an aggressive graded balloon dilatation approach is pursued.<sup>58,59</sup>

Although debated in the literature, the addition of a partial fundoplication to the myotomy results in similar efficacy but reduced rates of reflux, with rates of 31.5% after a myotomy alone versus 8.8% when combined with a partial fundoplication.<sup>61</sup> This was echoed in a small, prospective randomized trial showing reflux rates after a Heller myotomy of 47.6% versus rates after

a Heller combined with (anterior) Dor fundoplication of 9.1%, with similar clinical efficacy for the two procedures.<sup>62</sup> However, a complete fundoplication (Nissen) combined with myotomy is not recommended, as rates of dysphagia were significantly higher postoperatively in a prospective trial evaluating this approach.<sup>63</sup>

### Peroral Endoscopic Myotomy

POEM is the newest treatment option available for achalasia and was first conceived by Pasricha in 2007<sup>64</sup> and first performed by Inoue<sup>65</sup> in a human subject shortly thereafter. The concept is to create a submucosal tunnel that allows direct visualization of the circular muscle layer in the esophagus, to advance the submucosal tunnel to below the gastroesophageal junction, and then to perform a selective myotomy beginning approximately 3 cm distal to the EGJ (to include the gastric sling and clasp fibers), extending proximally as needed. The endoscope is then removed from the submucosal tunnel and the mucosal defect is closed using endoscopic clips (Videos 19.1–19.4).<sup>66</sup> POEM has the theoretical advantage of allowing direct access to the circular muscle layer of the esophagus without the need to enter the abdominal or thoracic cavities, resulting in no skin incisions and faster recovery. POEM also has the benefit of not being limited to either above or below the diaphragm, as is the problem if either a laparoscopic or thorascopic surgical approach is chosen. However, the two disadvantages of POEM are (a) lack of true long-term data, as this is a relatively novel procedure, and (b) higher reported rates of reflux, as the endoscopic procedure cannot currently be combined with an anti-reflux procedure. Although well over 5000 procedures have been performed worldwide, most of these have been performed in Asia. POEM is currently limited to specialty centers and is not as widely available as the other therapies mentioned earlier.

The published efficacy and safety of POEM have been evaluated in several recent systematic reviews, many including outcomes from over 1000 cases.<sup>67–70</sup> Efficacy is difficult to quantify because of study heterogeneity, but one systematic review evaluating 16 studies with a total of 551 patients reported technical and clinical success rates of 97% and 93%, respectively.<sup>68</sup> However, most of the included patients were published in retrospective analyses and no randomized controlled trials were included. Published short-term results have invariably been very good, with most centers reporting a greater than 90% clinical success rate.<sup>71</sup> Long-term data are more limited. Inoue (2015) published long-term outcome data for his first 500 POEM cases, with an overall success rate of 88.5% at a minimum interval follow-up of 3 years.<sup>72</sup> A 24-month outcomes study of 205 patients with achalasia who underwent POEM at 10 tertiary care centers across the world reported clinical success (defined by an Eckardt score < 3) in 98% at 6 months, 98% at 12 months, and 91% at 24 months or more.<sup>73</sup> Less optimistically, a 2-year follow-up study of 85 patients treated with POEM at three academic centers reported an initial clinical response in 96.3%, but recurrence in a 2-year period in an additional 18% of patients (resulting in a total success rate of 79% at 2 years).<sup>74</sup> A multicenter randomized, prospective study (2017) comparing POEM with pneumatic dilatation in 133 patients with treatment-naïve achalasia reported POEM success rates of 98.4% at 12-week follow-up and 92.2% at 1 year.<sup>75</sup> To our knowledge, this is the first prospective randomized controlled trial evaluating POEM versus another treatment modality for achalasia.

Safety of POEM appears to be excellent. In a recent evaluation of 1826 patients who underwent POEM at 12 tertiary care centers

between 2009 and 2015, adverse events were noted in 137 patients (7.5%); however, the bulk of these were judged to be mild, and severe adverse events were only seen in 9 patients (0.5%). The most commonly reported adverse events were inadvertent mucosotomy and adverse events related to insufflation. Only four patients (0.2%) required surgery for bleeding during tunneling, mucosotomy, esophageal leak, or empyema, and no fatalities were reported.<sup>70</sup>

Perhaps the most significant concern regarding POEM is the potential for abnormal gastroesophageal reflux following the procedure, given that it certainly seems effective at LES disruption without being combined with an anti-reflux procedure. A study of 100 treated patients after POEM reported a short-term clinical success of 94%, but 24-hour pH monitoring demonstrated pathologic esophageal acid exposure in 53.4% of patients, a minority of them with heartburn (24.3%) or esophagitis (27.4%).<sup>70,71</sup> Of note, all the symptomatic patients were well controlled with medical therapy. In two systematic reviews, the post-POEM reflux rates were estimated to range from 10% to 19%<sup>70,71</sup>; however, relatively few of these studies performed pH monitoring, and these numbers were largely based on symptoms and endoscopic appearance for those few patients who underwent postprocedure endoscopy. In the 2017 multicenter randomized prospective study comparing POEM to pneumatic dilatation, all subjects underwent pH monitoring and endoscopy at 1-year post-POEM. In this series, abnormal esophageal acid exposure was noted in 49.1% of POEM patients versus 38.6% of pneumatic dilatation patients. However, significantly more patients with severe reflux esophagitis (Los Angeles C or D) were seen in the post-POEM group.<sup>72</sup> Whether this higher acid exposure has clinical relevance is unknown, but is worth following as more data become available in the future.

Whereas POEM can be considered as a treatment option for all patients with achalasia, it may have a special niche for treatment of those patients with type III, or spastic, achalasia. As POEM is not limited by the diaphragm, one has the option of creating a long myotomy in conjunction with a standard sphincter-disruption procedure. In a retrospective analysis of 49 patients with type III achalasia who underwent POEM at eight academic centers versus 26 patients who underwent laparoscopic Heller myotomy at a single center, POEM resulted in clinical success in 98% of patients versus 80% with surgical myotomy. The average POEM myotomy length was 16 cm, versus an average Heller myotomy length of 8 cm.<sup>73</sup>

The data regarding POEM for treatment of achalasia is rapidly emerging, and its role is evolving. At present, POEM is a reasonable option for any patient with achalasia if local expertise exists. For those with type III achalasia, POEM may be preferable to other modalities because a long myotomy is appealing and makes physiologic sense. For those patients with type II achalasia, POEM remains a very reasonable option, but there are no data at present to suggest that POEM is superior to surgery in terms of efficacy. For this reason, the decision as to which modality to employ for those patients with type I or type II achalasia depends on many factors, including local expertise, patient preference, and likelihood of postprocedure reflux.

### Stent Placement

Placement of an esophageal self-expanding metal stent is not typically considered in the treatment algorithm; however, based on data from China, it is a potential option that can be considered in extenuating circumstances.<sup>74-76</sup> In 2009, Zhao and colleagues

reported a series of 75 patients with achalasia who were treated with a 30-mm esophageal stent. Stents were placed under fluoroscopic guidance and removed approximately 5 days later. Clinical response was reported to be 100% at 1 month and 83% at 10 years.<sup>74</sup> No perforations were reported. Investigators from Italy utilized temporary placement of a 30-mm stent in 7 patients with achalasia, and reported complete symptom resolution in 5 and marked symptom improvement in 2, without complications.<sup>75</sup> Most recently, investigators from Shanghai (2016) evaluated stent placement versus balloon dilatation in 77 patients with achalasia, and reported increased short-term efficacy and decreased recurrence in patients treated with stent placement in comparison to balloon dilatation.<sup>76</sup> More data are needed to support this thought-provoking and apparently efficacious approach.

### Esophagectomy

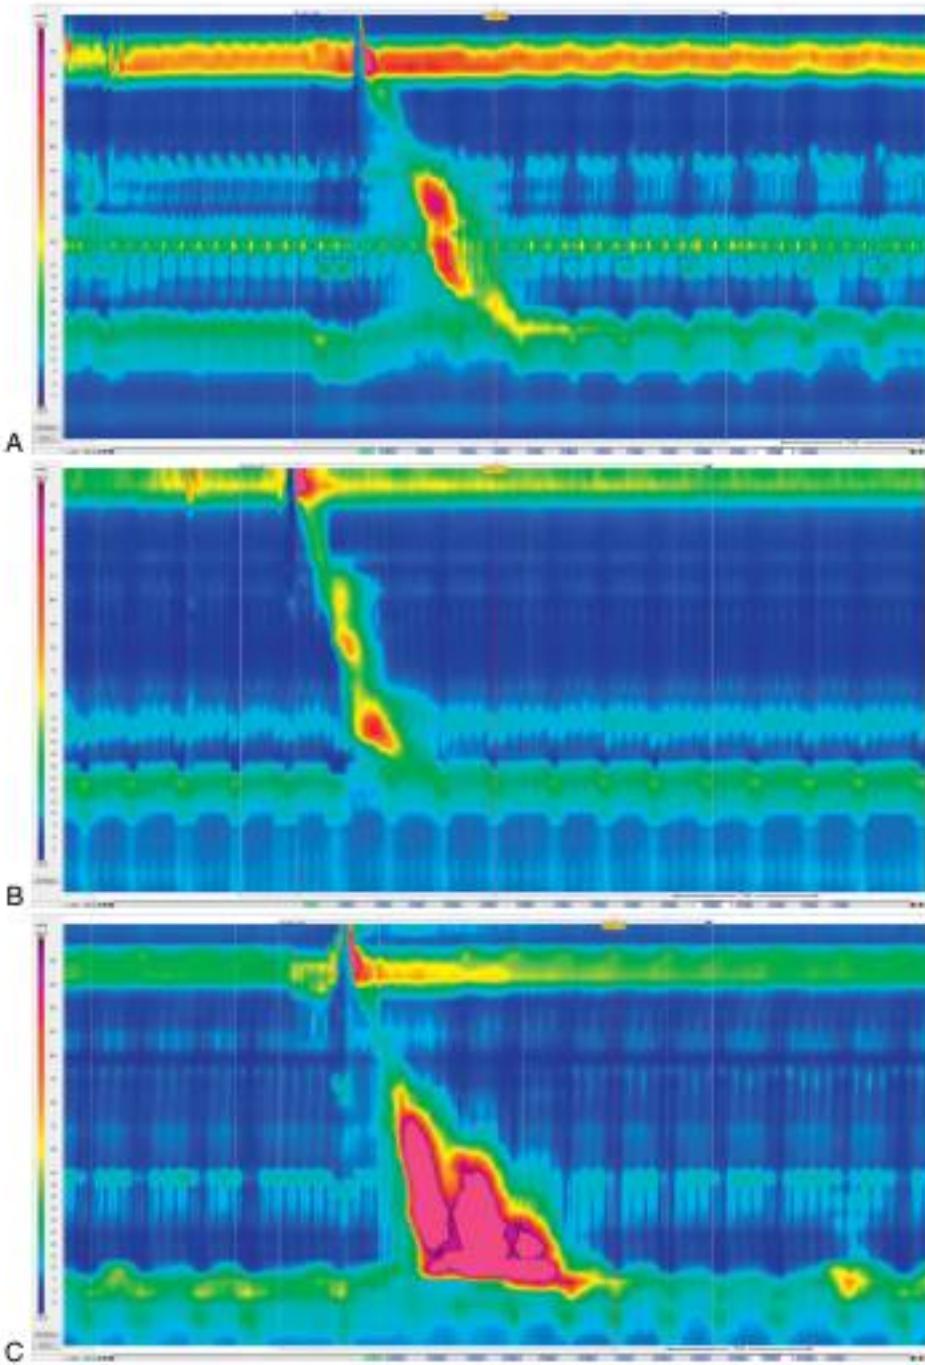

Approximately 5% of achalasia patients will eventually require esophagectomy either because of pronounced esophageal dilatation, severe dysphagia despite appropriate therapy directed at the LES, a peptic stricture that is not amenable to dilatation, or complications related to esophageal dilatation/aspiration or surgical intervention, or esophageal cancer. Several options are available for patients who reach this point, including a distal segmental esophagectomy, vertical esophagectomy and myotomy, vagal-sparing esophagectomy, and subtotal esophagectomy. Each of these procedures has pros and cons, with subtotal esophagectomy being the most commonly performed today for end-stage achalasia.<sup>77</sup> Although certainly a reasonable option in the appropriate patient, esophagectomy has greater morbidity and mortality than other therapies and is generally viewed as a last resort. In a 2014 analysis of 963 patients with achalasia who underwent esophagectomy, the median length of hospital stay was 13 days, with a cost of \$115k and a mortality rate of 2.7%.<sup>78</sup>

## OTHER MOTILITY DISORDERS

There are many patients who have significant symptoms suggestive of dysmotility with abnormal objective testing, but who do not meet the current Chicago criteria for achalasia. These patients are typically classified by their manometry pattern into the following categories: EGJ outflow obstruction, distal esophageal spasm, and hypercontractile esophagus. Each of these is seen frequently in practice, but treatment options are less well defined than for achalasia. Although not considered a major motility disorder, we will also touch on IEM, which is frequently seen in evaluation and is of uncertain clinical significance (Fig. 19.5).

### EGJ Outflow Obstruction

EGJ outflow obstruction is defined by the Chicago Classification as impaired relaxation of the LES (defined by an elevated IRP  $> 15$  mm Hg) with preserved peristalsis.<sup>31</sup> This pattern has uncertain clinical significance and appears to be a clinically heterogeneous rather than a uniform process. The first significant description of EGJ outflow obstruction came from Scherer et al at Northwestern University in 2009, who identified 16 patients from 1000 consecutive manometrics. They noted that these patients had dysphagia and/or chest pain and responded to sphincteric disruption therapy, specifically Heller myotomy. They concluded that in some cases, functional EGJ outlet obstruction may represent a variant of achalasia with incomplete manometric manifestations.<sup>79</sup> In a series of 34 patients, Van Hoeij et al (2015) from Amsterdam (The Netherlands) reported that 82% required

**FIG 19.5** High-resolution manometry examples of major motility disorders. **A**, Typical image of esophagogastric junction (EGJ) outflow obstruction (with impaired EGJ relaxation but preserved peristalsis). **B**, Typical image of distal esophageal spasm (with a short distal latency and rapid contraction). Of note, this can be relatively subtle and may be missed if not looking at the distal latency specifically. In this swallow, the distal latency was 3.9 seconds (normal < 4.5 seconds). **C**, Typical image of a hypercontractile esophagus, with classic jackhammer appearance.

no treatment and over half of the patients had symptoms judged unrelated to the manometric obstruction. Three patients progressed to achalasia on subsequent evaluation. They concluded that the clinical significance of EGJ outflow obstruction was unclear, that a substantial subset has unrelated symptoms, and that spontaneous improvement is not uncommon.<sup>65</sup> In another

series of 44 patients, over 30% had spontaneous resolution of symptoms without treatment directed at the EGJ and cautioning that invasive treatments may not be needed.<sup>66</sup> In 2016, investigators from South Florida evaluated 49 patients with EGJ outflow obstruction, noting that 27 patients had functional issues, whereas 22 patients had an anatomic abnormality (most commonly

strictures and hiatal hernias). Manometry and barium esophagram studies did not distinguish the two groups, but they behaved distinctly due to their different underlying etiologies.<sup>30</sup> In the largest series yet, patients who met criteria for EGJ outflow obstruction were a hodgepodge of different clinical subgroups, including patients with unrelated symptoms (identified incidentally, for instance, on a manometry performed to evaluate for reflux), anatomic abnormalities (particularly hiatal hernias), and patients with potential variant achalasia.<sup>34</sup> Interestingly, EGJ outflow obstruction was more frequently seen in patients who had used opiates within the past 24 hours (27%) compared with controls (7%).<sup>31</sup>

When all these series are taken in context, one is left with the question of how to approach a symptomatic patient with EGJ outflow obstruction identified by manometry. In our practice, we generally take the following steps. First, given the known association with opiate use and EGJ outflow obstruction, we ensure that patients are not taking opiates and there are no potential medicinal causes for the manometric finding. Second, due to recognition that EGJ outflow obstruction is a mixture of patients with anatomic abnormalities and functional issues, we perform complementary testing (endoscopy with biopsies, barium esophagography, FLIP) to evaluate for hiatal hernias, subtle strictures, and infiltrative processes, particularly eosinophilic esophagitis. Third, due to reports linking EGJ outflow obstruction to neoplasm in rare cases, we ensure that there has been appropriate imaging (either via CT/magnetic resonance imaging or endoscopic ultrasound) if no alternative etiology is found to explain the findings and it is clinically appropriate. If, after the aforementioned, no underlying etiology is found to explain the manometric findings, abnormality is corroborated on complementary testing, and the patient has symptoms significant enough to warrant intervention, then we consider therapy aimed at reduction in LES pressure (smooth muscle relaxants, botulinum toxin injection, pneumatic dilatation, myotomy). As symptoms and findings may abate spontaneously, we start with less invasive options upfront (medical therapy or botulinum toxin injection), with other interventions reserved for those with persistent findings and significant symptoms. We have referred select patients with EGJ outflow obstruction for definitive intervention (pneumatic dilatation, POEM, and Heller myotomy) with excellent outcomes, but only after careful deliberation and extensive evaluation.

### Distal Esophageal Spasm

Esophageal spasm is commonly considered as a diagnosis for patients with dysphagia and chest pain but rarely proven on manometry. Esophageal spasm was first described clinically in 1889 and first documented by manometry in 1958.<sup>32,33</sup> Utilizing conventional manometry, spasm was defined by the presence of rapid conduction velocity, simultaneous contractions, or multiphasic contractions.<sup>34</sup> However, with the advent of HRM, these findings have been found to be non-specific. In 2011, Pandolfino and colleagues proposed that spasm be diagnosed based solely on distal latency (essentially the time between upper esophageal sphincter relaxation and when the deglutive contraction reaches the distal esophagus) after showing that this was a more specific finding than the contractile front velocity. A cutoff of 4.5 seconds for 20% or more of wet swallows was proposed.<sup>35</sup> This quantification of spasm was subsequently adopted in the Chicago Classification and is the basis of the manometric diagnosis of distal esophageal spasm today.<sup>31</sup>

Medical options for treatment of esophageal spasm are relatively limited. To compound the issue, most published studies rely on conventional manometric criteria for esophageal spasm, which in the days prior to HRM, likely represented a heterogeneous collection of different manometric phenotypes (as classification could be based on velocity, simultaneous contractions, and multiphasic contractions). The mainstay of medical therapy for distal esophageal spasm has been smooth muscle relaxants, specifically calcium channel blockers,<sup>36</sup> nitrates,<sup>37,38</sup> and phosphodiesterase inhibitors.<sup>39</sup> However, data are limited to small case series and there are no randomized controlled trials that show efficacy at the present time. Anecdotally, pharmacologic therapy for spasm has been disappointing; however, it is still a reasonable first-line treatment for symptomatic patients with documented or suspected esophageal spasm. In our practice, we often start with low-dose calcium channel blockers taken 15 minutes before meals or sublingual nitroglycerin taken as needed during episodes.

If symptoms persist despite medical therapy, then botulinum toxin injection is a reasonable next step, with the hypothesis that blockage of acetylcholine release from excitatory neurons will weaken esophageal contractions and improve symptoms. This was evaluated in a randomized controlled trial of 22 patients with either distal esophageal spasm or a hypercontractile esophagus. Patients underwent injection in two regions, immediately proximal to the EGJ and in the esophageal body. Fifty percent of patients responded to botulinum toxin, as opposed to only 10% of controls at 1 month, and in the subgroup analysis the distal esophageal spasm patients were noted to have significant improvement in dysphagia and symptoms scores.<sup>40</sup> However, it should be noted that there are no long-term studies evaluating the efficacy of repeated botulinum toxin injection for spasm, and botulinum toxin, although considered relatively safe, is not risk free. In a 2017 analysis of 386 patients undergoing 661 botulinum toxin injections for treatment of esophageal motility disorders (51% achalasia, 30% spasm), 7.9% developed mild complications (chest pain, heartburn, or epigastric pain in the majority of cases), and 1 patient developed a fatal acute mediastinitis.<sup>41</sup>

Finally, POEM has been evaluated as a potential option. This has been proposed for patients with significant symptoms in the context of well-documented spasm refractory to medical intervention. POEM offers the theoretical ability to cut esophageal musculature and prevent contractions in a more durable fashion than achieved with botulinum toxin injection. A 2017 systematic review and meta-analysis evaluated 8 observational studies including 179 patients with spastic esophageal disorders. Of that group, 18 were identified to have distal esophageal spasm. The weighted pool rate for clinical success of POEM in these patients was 88%, and the weighted pool rate for adverse events was 14%.<sup>42</sup> Long surgical myotomy has also been reported for treatment of esophageal spasm,<sup>43,44</sup> but data are limited and this appears to have fallen out of favor with the advent of POEM. More data are needed to better stratify which patients require and benefit from more invasive intervention.

### Hypercontractile Esophagus

Hypertensive peristaltic contractions are commonly encountered at manometry. These were initially labeled as *nutcracker esophagus* based on seminal work from Castell et al (1987, 2006), and were hypothesized to cause chest pain and dysphagia.<sup>50,51</sup> However, data regarding symptom causality were contradictory, and these values were also found in patients with reflux and healthy asymptomatic controls. With the advent of HRM, terminology changed

to provide greater specificity. Initially the terms *hypertensive peristalsis* and *spastic nutcracker* were used to signify patients who may have been previously labeled as nutcracker esophagus.<sup>29</sup> However, investigators from Northwestern University subsequently coined the label *jackhammer esophagus* to signify a degree of hypercontractility never seen in healthy controls. In their seminal publication, they evaluated 72 healthy asymptomatic controls in comparison to 2000 patients. Using the distal contractile integral (DCI) as a marker of esophageal contractile vigor, they found that a cutoff of more than 8000 mm Hg/s per cm for a single swallow exceeded the peak DCI of any healthy control and seemed pathologic. As most of these hypertensive aberrant contractions were multi-peaked, they coined the term *jackhammer esophagus* as a visual description of the contraction. To qualify for this diagnosis, patients had to have a single swallow with a DCI greater than 8000 mm Hg/s per cm in the context of normal LES relaxation and normal distal latency (excluding achalasia or spasm).<sup>30</sup> The term *nutcracker esophagus* was used in the second version of the Chicago Classification to refer to hypertensive peristaltic contractions not fulfilling criteria for jackhammer esophagus, but then was subsequently removed.<sup>31,32</sup> In the most recent third version of the Chicago Classification, the criteria for a hypercontractile esophagus were tightened to include a DCI greater than 8000 mm Hg/s per cm for at least 20% of wet swallows to increase specificity.

Treatment options for a hypercontractile esophagus are the same as those for esophageal spasm. Most publications evaluating treatment for esophageal hypercontractility were published before the term *jackhammer esophagus* was coined and likely included numerous manometric subgroups. Specifically, the multi-peaked contractions seen frequently in jackhammer esophagus previously would have satisfied criteria for distal esophageal spasm using conventional manometric criteria.<sup>33</sup> As such, nitrates, calcium channel blockers, and sildenafil can all be considered, but there are no randomized controlled trials evaluating any medical options for the treatment of jackhammer esophagus. Botulinum toxin injection has also been employed with some success, similar to that reported for spasm. Marjoux et al (2015) reported clinical success in 5 out of 7 patients with jackhammer esophagus at greater than 6 months.<sup>30</sup> In the randomized trial detailed earlier showing efficacy of botulinum toxin in spastic disorders, Vanuytsel et al (2013) included 7 patients with a hypercontractile esophagus; however, subgroup analysis of these 7 patients was not reported.<sup>34,35</sup> POEM has also been employed with some success. In a 2017 systematic review evaluating POEM in the context of spastic esophageal disorders, 8 observational studies with 179 patients were identified. In the 37 patients with jackhammer esophagus who underwent POEM, the weighted pooled rate for clinical success was 72%, and the weighted pooled rate for postprocedure adverse events was 16%.<sup>30</sup> Akin to distal esophageal spasm, more data are needed to make concrete recommendations as to the best management for these patients.

### Ineffective Esophageal Motility

IEM was defined by the third Chicago Classification as low-amplitude contractions (DCI < 450 mm Hg/s per cm) in 50% or more of wet swallows, and is synonymous with weak peristalsis.<sup>31</sup> Although the manometric criteria for this diagnosis are clearly defined, etiology, pathophysiology, and clinical significance remain uncertain. As opposed to the major motility disorders detailed earlier, IEM is labeled as a minor motility disorder,

meaning that, whereas it may be associated with symptoms in some patients, the pattern also can be found in healthy asymptomatic controls. Recently, Castell et al (2017) reviewed their experience with 231 IEM patients, relating an association with abnormal esophageal acid exposure and suggesting different clinical subgroups within the broader IEM umbrella.<sup>36</sup> Although a significant impairment of bolus clearance is seen in symptomatic patients with gastroesophageal reflux disease and IEM, such patients are otherwise indistinguishable from those with acid reflux symptoms and normal motility.<sup>37</sup>

Patients with IEM can pose a significant clinical challenge, and data on specific treatments is limited. Given the uncertain clinical significance of this manometric finding, lifestyle modifications are a reasonable first step. Proposed modifications include ensuring an upright position during mealtime, sufficient chewing, intake of carbonated beverages, effortful swallowing, and decreased bolus consistency. If reflux-related symptoms are dominant, then lifestyle, medical, and interventional therapy directed at reflux are recommended. The role of anti-reflux mechanical interventions in the context of IEM is controversial and outside the scope of this chapter. There are no medical options that have been clinically studied specifically for IEM; however, several medications have been shown to enhance esophageal contractility, including bethanechol, pyridostigmine, metoclopramide, domperidone, prucalopride, and buspirone.<sup>38</sup> At present, however, usage of all these medications for IEM would be off label and there are no published studies showing long-term efficacy for symptoms related to IEM with any specific medical therapy at present. There are no data to suggest benefit with either endoscopic or surgical approaches.

### NOVEL ENDOSCOPIC APPLICATIONS

Improvements in endoscopic technology have opened frontiers previously unknown. POEM has evolved from conceptualization to full implementation around the globe in under a decade. In addition, submucosal tunneling has become more widely available, making the submucosal space more readily accessible for interventions beyond a simple myotomy. Biopsies are now feasible during POEM, allowing direct access to the muscularis propria. In addition, novel diagnostic tools that may be less invasive, such as endocytoscopy, are also potential additions to the diagnostic armamentarium.<sup>39</sup> Given how much is still unknown regarding the etiology and pathophysiology of achalasia and other motility disorders, the ability to get directed samples from the affected tissues via submucosal tunneling offers great potential to hopefully increase our understanding of these disorders, and potentially suggest future therapies that will be disease modifying rather than palliative.

In addition to directed deep-biopsy acquisition and in vivo evaluation, the other key potential offered by esophageal submucosal tunneling is the ability to directly implant devices and drugs in the deep layers of the esophagus. Investigators from Johns Hopkins evaluated the blind insertion of a microstimulator in the distal esophagus of a canine model approximately a decade ago.<sup>40</sup> However, with the advent of submucosal tunneling, targeted delivery of these devices will become feasible and may potentially be less invasive and safer than surgically implanted devices that run the risk of lead migration. Likewise, targeted drug delivery (presently speculative) may allow local action of select medications, leading to potentially greater efficacy and less systemic side effects.

## FUTURE DIRECTIONS

The past decade has seen rapid development in the use of diagnostic technologies including HRM, impedance, and FLIP, as well as rapid expansion in endoscopic therapies, and, in particular, POEM. However, there are still many basic questions regarding esophageal motility disorders that have not yet been answered. FLIP topography seems poised to change the diagnostic landscape of esophageal motility disorders within the next few years, and may lead to greater understanding of physiology and symptom pathogenesis. Long-term data regarding POEM are emerging, and we expect a greater understanding regarding the relative pros and cons (particularly with regard to acid reflux) of this approach compared with other modalities. Randomized controlled trials comparing POEM with laparoscopic Heller myotomy are currently underway. Ultimately, however, many big questions remain regarding disease pathogenesis and etiology, and with increased technology and the accessibility of the submucosal space we are hopeful that some of those questions can be answered.

## CONCLUSION

Esophageal motility disorders are frequently encountered in gastroenterology practices today, with achalasia being the most prominent. Utilizing endoscopy, fluoroscopy, and manometry, most patients can be successfully diagnosed and receive prognostic information regarding optimal treatment. For a handful of patients with conflicting information, FLIP and, potentially, impedance may offer additive information. For most patients, treatment of achalasia should be with definitive therapy, specifically pneumatic dilatation, Heller myotomy, or POEM, all of which have their selling points and are reasonable options based on patient specifics and local expertise. Other major motility disorders of the esophagus, including EGJ outflow obstruction, distal esophageal spasm, and the hypercontractile esophagus, have less defined treatment algorithms and should be evaluated on a case-by-case basis.

## INTRODUCTION

Zenker's diverticulum (ZD) is a posterior pharyngoesophageal mucosal outpouching that forms through Killian's triangle. Poor upper esophageal sphincter (UES) compliance is the acknowledged pathophysiologic mechanism of action, leading to creation of a high-pressure zone, ultimately resulting in diverticulum formation. This entity most commonly presents in the elderly, and can be associated with a plethora of potential symptoms, most commonly dysphagia. Cricopharyngeal myotomy is usually performed alone or in combination with diverticulectomy (when open surgery is performed) to improve symptoms and prevent recurrence.

## CLINICAL PRESENTATION AND DIAGNOSIS

ZD most frequently occurs between the seventh and eighth decades of life, predominantly in men.<sup>1–4</sup> ZD is rarely identified before the age of 40 years. The overall prevalence in the general population is between 0.01% and 0.11%, and varies markedly throughout the world. However, these data reflect symptomatic patients, and the number of asymptomatic patients with ZD remains unknown. Anatomical differences or life expectancy may account for the varying prevalence between geographic areas.<sup>5</sup> In the United Kingdom, the incidence of ZD is approximately 2 per 100,000 people per year.<sup>6</sup> It has been described more commonly in the United States, Canada, and Australia than in Japan and Indonesia.<sup>7</sup> Symptoms may be present for weeks to years before diagnosis.<sup>8</sup> Cervical borborygmus, in the presence of a palpable lump in the neck, is nearly pathognomonic for ZD. Although a multitude of symptoms have been attributed to ZD, 80–90% of patients suffer from dysphagia. Dysphagia occurs secondary to incomplete opening of the UES and extrinsic compression of the cervical esophagus by the diverticulum itself. As the pouch enlarges and dysphagia increases, symptoms often worsen, leading to resultant weight loss and malnutrition. A sudden increase in symptom severity and/or the development of alarming symptoms such as local pain, hemoptysis, or hematemesis may signal the presence of ulceration<sup>9</sup> or squamous

cell carcinoma within the diverticulum. Squamous cell carcinoma arising in a ZD is said to have an incidence of 0.4–1.5%,<sup>10</sup> though these older data might reflect more long-standing, untreated disease. Presumably, therapy decreases stasis and risk of cancer. Additional symptoms such as hoarseness/dysphonia, regurgitation, halitosis, cough, and aspiration pneumonia have been described in 30–40% of patients.<sup>11</sup> It is unclear if pneumonia occurs due to direct aspiration of diverticular contents or aspiration of contents pooled within the pharynx.<sup>12</sup> Medications (i.e., capsules, tablets) can become entrapped in the diverticulum, leading to decreased efficacy and, potentially, ulceration with bleeding.<sup>13</sup> Entrapment of a video capsule within a ZD has also been reported.<sup>14,15</sup> Gastrointestinal bleeding within the diverticulum can occur, and is amenable to endoscopic management.<sup>15,16</sup>

A variety of other conditions have been associated with ZD. These include laryngocoele, leiomyoma, polymyositis, cervical esophageal web, carotid body tumor, postanterior cervical disectomy and fusion, upper esophageal stenosis, hiatal hernia, and gastroesophageal reflux disease.<sup>17</sup>

## PATHOPHYSIOLOGY

The UES is composed of the posterior surface of the thyroid and cricoid cartilage, as well as three muscles: the inferior pharyngeal constrictor, cricopharyngeus (CP), and cervical esophagus.<sup>18</sup> Of these three muscles, the CP provides for the dominant portion of UES function. It forms a muscular sling around the upper esophagus between the two sides of the cricoid cartilage and extends posteriorly to mesh with the inferior pharyngeal constrictor. Two sets of CP muscle fibers have been identified: the horizontally oriented fibers that occlude the esophageal introitus, and an oblique band of fibers that are responsible for propulsion of the bolus.

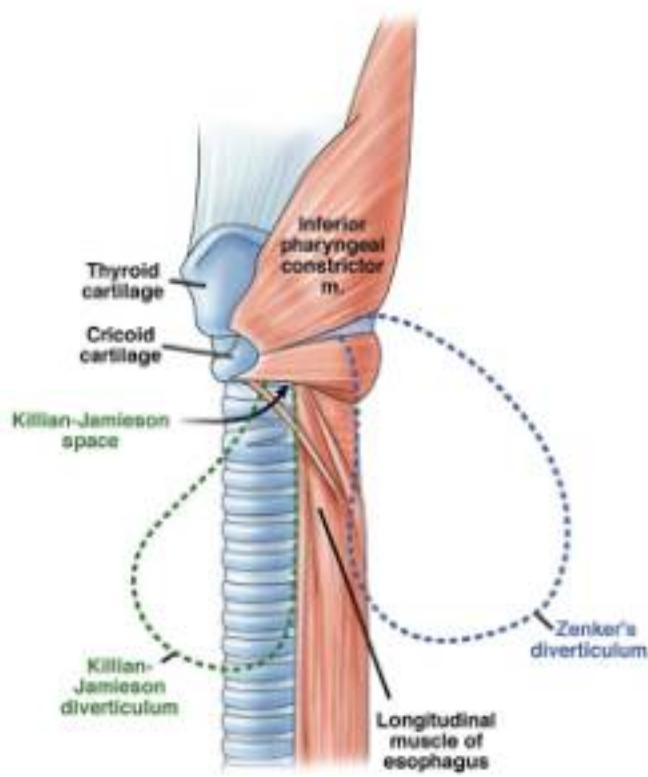

The inciting pathophysiologic mechanism of ZD is inadequate UES sphincter compliance with failure to open completely.<sup>19</sup> This failure to achieve adequate diameter for effective bolus clearance leads to increased intraluminal pressure with outpouching in an area of relative wall weakness in the hypopharynx

**Abstract**

Zenker's diverticulum (ZD) is an outpouching of tissue through Killian's triangle thought to be due to cricopharyngeal muscle dysfunction. This relatively uncommon disorder, which occurs more commonly in the elderly, presents with symptoms of dysphagia. Videofluoroscopy confirms the diagnosis. Therapy of symptomatic ZD has evolved from an open surgical approach to transoral endoscopic techniques. Transoral endoscopic therapy includes the rigid approach performed primarily by otorhinolaryngologists and the flexible approach performed by surgical endoscopists and gastroenterologists. The common goal of all treatments is dividing the septum between the esophageal lumen and the diverticular lumen. Each approach has variations in techniques, as well as advantages and disadvantages. In this chapter, we will outline the pathophysiology and management of patients with Zenker's diverticula, with an emphasis on flexible endoscopic therapy.

### Left lateral view

**FIG 20.1** Illustration of Zenker's diverticulum as a herniation through Killian's triangle. *m.*, muscle. (From Law R, Katzka DA, Baron TH: Zenker's diverticulum. *Clin Gastroenterol Hepatol* 12[11]:1773-1782, 2014.)

between the CP and inferior pharyngeal constrictor. This area, known as Killian's Triangle, is adjacent to the retropharyngeal space and thus leads to pouch formation posteriorly (Fig. 20.1). The diverticulum may be posterior, posterolateral, or lateral (pharyngocoele), but the most common subtype is the posterior pulsion diverticulum.<sup>19</sup> ZD most commonly forms posteriorly on the left side. This is important for determination of the neck incision site during an open surgical approach and when performing endoluminal therapy, as division of the common wall between the diverticulum and the esophageal lumen is necessary for complete symptom relief. It should be noted that this posterior pouch includes only mucosa and submucosa; therefore a ZD should be considered a "pseudo-diverticulum." Several other factors may contribute to pharyngoesophageal pouch formation. For example, increased intrabolus pressures have been well documented, and likely occur due to stiffness of the CP and hypopharynx. Increased intrabolus pressure is also increased in older patients who perform multiple swallows to achieve bolus clearance. Moreover, as the diverticulum enlarges, it may compress the pharyngoesophageal segment and lead to increased intrabolus pressure secondary to extrinsic compression. Finally, incoordination of pharyngeal contraction and UES opening has also been variably demonstrated by some investigators.<sup>15</sup> Video fluoroscopy is a valuable tool, particularly for diagnosis, but precise determination of abnormal function is limited by variation in interpretation and quality. Furthermore, useful manometric data are exceedingly

### BOX 20.1 Bromberg Classification of Zenker's Diverticulum

- Stage I:** Thorn-like with longitudinal axis of 2–3 mm visible during the contraction phase of the upper esophageal sphincter after deglutition but not during deglutition
- Stage II:** Cub-shaped with longitudinal axis of 7–8 mm visible during the contraction phase of the upper esophageal sphincter
- Stage III:** Bag-shaped with a caudally-oriented axis of more than 1 cm but without compression of the esophagus
- Stage IV:** Large with compression of the esophagus

difficult to obtain in this area, due to asymmetry in sphincter pressures and wide variations in sphincter motility during swallowing.

### DIAGNOSTIC EVALUATION

A diagnosis of ZD is most commonly obtained via radiography in conjunction with videofluoroscopy (Fig. 20.2). The defect is best seen during the act of swallowing in the lateral view. Evidence of aspiration may be seen as contrast is cleared from the diverticulum. Static images are often inadequate in patients with a small diverticulum. The size of the diverticulum may vary considerably. Early stage diverticula may be 1 cm or less and difficult to appreciate; however, ZDs as large as 6 cm have been reported.<sup>20</sup>

The Brombart classification scheme (Box 20.1) defines four types of ZD based on findings from barium esophagography. The original concept of this little-known staging system was that patients progressed from one stage to another.<sup>21</sup> Although this hypothesis has not been validated, the scheme has been used to assess response to therapy, with postprocedural residual diverticulum and contrast retention strongly associated with prolonged dysphagia in the early postoperative period.

ZD may also be diagnosed by transcutaneous ultrasonography. This technique may be useful in elderly patients who cannot tolerate barium esophagography, and in patients with a palpable neck mass on physical examination. During ultrasound, ZD appears as a pouch-shaped structure posteriorly at the level of the pharyngoesophageal junction.<sup>22</sup> Similar to videofluoroscopy, contrast can be given to the patient, but is not mandatory. Retention of contrast for longer than 3 minutes during ultrasound is consistent with a ZD. Other ultrasonographic findings include an increase in the lesion's size with water ingestion and focal heterogeneous echogenicity secondary to retained contents (i.e., fluid, retained food, etc.) within the diverticular sac. In the future, neck ultrasonography may play a more prominent role during assessment of the UES. In a 2013 study, transcutaneous ultrasound was able to identify the normal diameter of the closed UES, mean duration of opening and mean duration of displacement in the anterior and lateral directions.<sup>23</sup>

Differentiation from the Killian-Jamieson diverticulum is important. Killian-Jamieson diverticula are smaller and less common, and arise from the proximal anterolateral cervical esophagus, lying inferior to the CP. Endoscopic treatment of Killian-Jamieson diverticula has been reported.<sup>24</sup> It remains unclear if the efficacy and safety profile of endoscopic therapy parallel those seen with ZD. It should be noted that the recurrent laryngeal nerve often runs in close proximity to the base of a Killian-Jamieson diverticulum.

**FIG 20.2** Radiographic images of Zenker's diverticulum. **A**, Frontal view; **B**, Lateral view.

## THERAPEUTIC OPTIONS

For decades, the treatment of ZD entailed an open surgical approach through a neck incision with subsequent myotomy of the UES and removal or suspension of the diverticulum.<sup>25</sup> Over the past four decades, alternative incisionless transoral approaches have been developed that utilize both rigid and flexible endoscopy. Most commonly performed by otorhinolaryngologists, rigid endoscopic therapy became popularized after a landmark study published by Dohlman and Mattison in 1960.<sup>26</sup> More recently, an increasing body of literature has demonstrated similar efficacy and safety using a flexible endoscopic approach, performed predominately by surgical endoscopists and gastroenterologists.<sup>27</sup>

### Open Surgical Approach

Open surgery resolves symptoms in 90–95% of patients.<sup>25</sup> For the open surgical approach, an external neck incision is made along the anterior border of the sternocleidomastoid muscle, typically on the left side, given the propensity of the pouch to emerge in this location. Frequently, this incision readily exposes the diverticulum. Dissection is performed to achieve adequate visualization of the neck of the diverticulum just below the inferior pharyngeal constrictor and the CP muscle. A myotomy is performed to access the proximal esophagus, thereby allowing treatment using one of three methods: inversion, resection or diverticulopexy. Larger diverticula (> 5 cm) typically require excision with closure of the defect using a linear stapling device. Moderate-sized diverticula can be treated with combined diverticulopexy and CP myotomy, whereas smaller diverticula are more frequently treated with CP myotomy alone. Potential adverse events of open surgery occur in 11% of patients, and include fistula formation, abscess,

hematoma, recurrent laryngeal nerve paralysis, difficulties in phonation, and Horner's syndrome.<sup>21</sup>

### Transoral Endoscopic Approaches

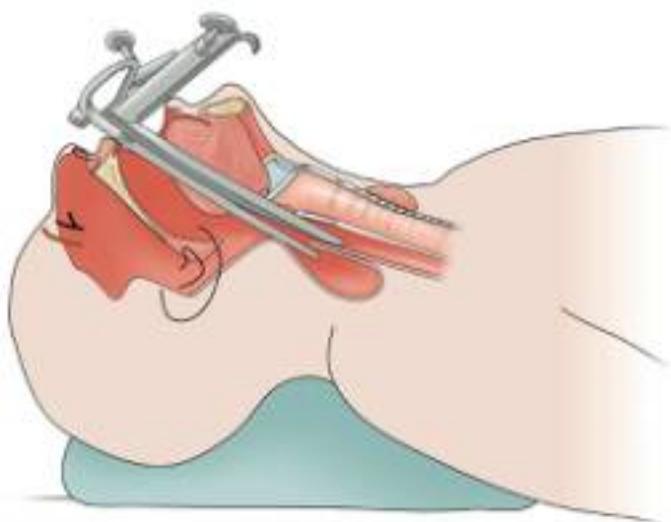

There are two types of endoscopic therapies for ZD: rigid and flexible. The common goal of both approaches is to sever the CP muscle (Fig. 20.3). The transoral endoscopic treatment for ZD was developed to mitigate the relatively high frequency (> 10%) of adverse events and mortality associated with the open approach. Although some adverse events are secondary to the frailty of elderly patients who frequently develop a pharyngeal diverticulum, many adverse events (i.e., leaks, fistulae, abscesses, etc.) are surgically related due to dehiscence/disruption of the suture/staple line with an inadvertent breach of the mucosa. Recent data from a meta-analysis and systematic review found that the endoscopic approach resulted in shorter procedure times, earlier diet introduction and lower rates of adverse events when compared to the open surgical approach.<sup>28</sup> However, higher rates of symptom recurrence were noted in patients undergoing endoscopic therapy.

### Rigid Endoscopic Approach

The rigid endoscopic approach is performed by passing a rigid (i.e., Weerda) diverticuloscope (Fig. 20.4), followed by dividing the common wall. Methods used to divide the common wall have evolved from electrocautery (known as Dohlman's technique) to CO<sub>2</sub> laser therapy to the now more commonly performed stapling, which cuts the septum and seals without causing tissue damage. Reports have also emerged on the use of ultrasonic scalpels to perform diverticulotomy.<sup>29</sup> These devices use ultrasonic energy to coagulate the septal tissue prior to division. Outcomes

**FIG 20.3** Flexible endoscopic cricopharyngeal myotomy for Zenker's diverticulum therapy. **A**, Endoscopic view with short, clear cap attached to endoscope tip. Nasogastric tube is in place and hook knife sheath is seen. **B**, Midpoint of the cricopharyngeal myotomy procedure. **C**, Completion myotomy. (From Law R, Katzka DA, Baron TH: Zenker's diverticulum. *Clin Gastroenterol Hepatol* 12[11]:1773–1782, 2014.)

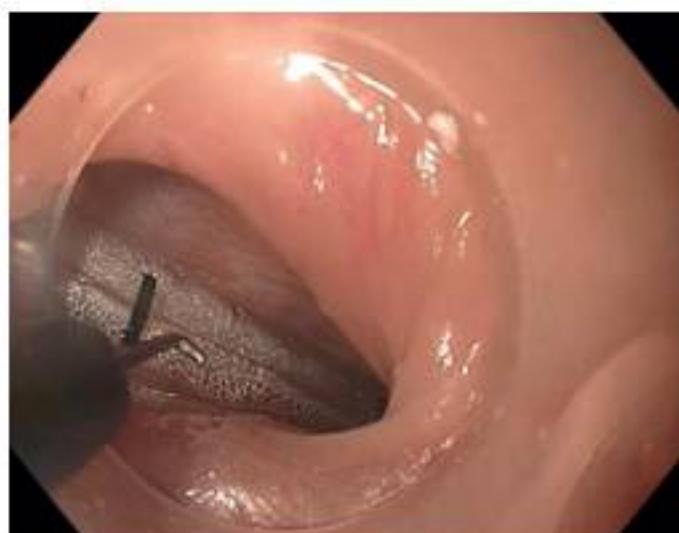

**FIG 20.4** Illustration of rigid endoscopic approach for Zenker's therapy. The patient's neck is hyperextended. A rigid diverticuloscope is inserted into the esophagus and Zenker's pouch to expose the septum. (From Law R, Katzka DA, Baron TH: Zenker's diverticulum. *Clin Gastroenterol Hepatol* 12[11]:1773–1782, 2014.)

of rigid endoscopic therapy, regardless of the incising device, demonstrate greater than 90% overall symptom improvement and a decreased rate of adverse events (< 10%) when compared to the open surgical approach. Adverse events specific to the rigid endoscopic approach include sore throat and gingival/mucosal laceration.

Transoral rigid endoscopic therapy cannot be performed in all patients due to inadequate exposure of the diverticulum. Historic data suggests that an open surgical approach is required in 15%–68% of cases when upper teeth protrusion, inadequate jaw opening, or insufficient neck mobility preclude rigid endoscopic therapy.<sup>23,30</sup>

### Flexible Endoscopic Approach

Due to the inherent limitations of the open surgical approach and the rigid endoscopic approach, a variety of techniques and

**FIG 20.5** Flexible endoscopic Zenker's diverticulotomy using a hook knife (Olympus America, Center Valley, PA).

methods have been developed to perform flexible endoscopic transoral cricopharyngeal myotomy (Video 20.1). Similar to other presented treatment options, the endoscopic technique aims to reduce cricopharyngeal sphincter pressure by dividing the CP muscle to the level of the diverticular apex.<sup>31</sup> Various dissection methods have been presented, including the use of endoscopic submucosal dissection (ESD) techniques and the creation of a diamond-shaped incision.<sup>32,33</sup> The septum (CP muscle) is commonly divided using needle-knives designed for pancreaticobiliary use and other electrocautery devices designed for ESD, such as a hook knife (Fig. 20.5).<sup>34</sup> Other methods used to divide the septum include monopolar and bipolar forceps, argon plasma coagulation, endoscopic scissor forceps (stag beetle knife, clutch cutter), harmonic scalpels, and stapling devices, the latter two of which are passed alongside a slim, flexible endoscope and not through the standard-diameter flexible endoscope working channel.<sup>35–39</sup> The optimal cutting device remains unclear, as comparative trials in this arena are lacking. The key advantages

**FIG 20.6** Soft diverticuloscope (ZD overtube; ZDO-22-30, Cook Endoscopy, Winston-Salem, NC).

**FIG 20.7** Modified esophageal overtube for Zenker's diverticulotomy (Guardus, US Endoscopy, Mentor, OH).

of the flexible endoscopic approach lie in the flexibility and smaller diameter of the gastroscope as compared to the large, rigid scopes, features that are vitally important for treating patients with limited neck extension and/or jaw retraction. Flexible endoscopic intervention may be most suitable for elderly patients with comorbid medical conditions limiting surgical intervention. In rare instances, patient comorbidities limit even flexible endoscopic diverticulotomy. Finally, flexible endoscopic therapy can be performed without the use of general anesthesia. However, the use of anesthesia support is recommended, due to the potential need for acute airway protection. Some authors have noted that an average of 60 minutes is required to perform flexible cricopharyngeal myotomy.<sup>27</sup>

Although not Food and Drug Administration-approved in the United States, a soft diverticuloscope (Cook Medical, Cork, Ireland) can be used to stabilize the septum, improve visualization, and further guide the instrument of incision (Fig. 20.6). This overtube-like device is designed to mimic the rigid diverticuloscope and has duckbill flanges at the distal aspect: one short flange that is seated within the diverticulum, and one longer flange that is placed within the true esophageal lumen. The cricopharyngeal septum is then exposed and stabilized between the flanges. Positioning of a diverticuloscope may be challenging or impossible in patients with small diverticula. Other alternative accessories used to enhance visualization include transparent hoods or caps attached to the tip of the endoscope, which are readily available and used for other endoscopic interventions such as mucosal resection. Various attempts to modify an esophageal overtube or the clear distal attachment cap for the

purpose of Zenker's diverticulotomy have been previously described (Fig. 20.7).<sup>40,41</sup>

When the soft diverticuloscope is not used, we recommend the preprocedural placement of a nasogastric (NG) tube. The NG tube serves two purposes. Firstly, it serves as a guide to continually orient the endoscopist to the true esophageal lumen during the procedure. Secondly, the NG tube provides a method to deliver enteral nutrition in the event of an adverse procedural event such as perforation. Blind passage of an NG tube is not recommended. Our protocol is to pass a small-caliber endoscope transnasally to facilitate guidewire placement into the stomach. The endoscope is then removed, leaving the guidewire in place. A small hole is made in the distal tip of the NG tube using an 18G needle to allow guidewire passage, and the NG tube is passed into the stomach. This technique avoids the need for oral-to-nasal transfer of the guidewire.

Treatment of ZD using a transoral flexible endoscopic approach was first described more than 20 years ago.<sup>42,43</sup> Many case series of flexible endoscopic therapy have since been published, comprising more than 650 patients.<sup>44</sup> Available studies have demonstrated safety and efficacy using various techniques and devices, comparable to the observed outcomes using a rigid transoral approach.<sup>45</sup> A high rate of durable symptom relief (> 90%) with a low rate of endoscopically-evident diverticular recurrence/persistence can be achieved after one to two treatment sessions. The recurrence or persistence of clinical symptoms appears to be less than 20%, though no consensus definition of postprocedural clinical success exists. Logically, clinical success should be based solely on symptom improvement, and not on radiographic or

endoscopic findings, as evidence of a refractory septum and/or residual diverticulum does not correlate with symptom persistence or recurrence after intervention.

Based on the available literature, the median adverse event rate following flexible endoscopic therapy is approximately 5% (range 0%–38%). Postprocedural throat pain is nearly uniform and may require narcotic analgesics, usually for up to 72 hours. Bleeding is the most common intraprocedural event. This is generally self-limited, but if persistent can be controlled endoscopically using standard therapies (i.e., electrocautery devices, endoclip placement, epinephrine injection). Uncomplicated subcutaneous emphysema may represent a microperforation; however, this can also be seen due to air tracking within the submucosal plane in the absence of a perforation.<sup>47</sup> We recommend the use of CO<sub>2</sub> for insufflation in all patients undergoing therapy for ZD. Overall, patients should be followed closely, though subcutaneous emphysema in an asymptomatic patient does not mandate surgical intervention. The most dreaded adverse event is perforation, a relatively uncommon adverse event that can occur during flexible endoscopic therapy even when performed by skilled endoscopists. Data compilations have demonstrated a median rate of perforation and/or leak of 4%, regardless of whether or not endoclips are placed at the diverticular apex following myotomy.<sup>47,48</sup> Concern for frank perforation should prompt an oral contrast study using water-soluble contrast to document the presence or absence of extravasation. Alternatively, a computed tomography scan of the neck with oral contrast can be performed.

## TRAINING IN FLEXIBLE ENDOSCOPIC CRICOPHARYNGEAL MYOTOMY

Incorporation of the flexible endoscopic approach into clinical practice should only be undertaken by expert therapeutic endoscopists with training in advanced endoscopy and experience in advanced endoscopic techniques, and only after careful consideration of the risks and benefits of the procedure on a patient-to-patient basis. This is especially true because the relative rarity of patients does not allow inexperienced endoscopists to pass the learning curve. Specifically, expertise in the use of various electrocautery devices is necessary when performing Zenker's diverticulotomy. Many of the techniques and devices used during flexible endoscopic cricopharyngeal myotomy overlap with ESD and peroral endoscopic myotomy.<sup>27</sup> Therapeutic endoscopists with advanced training in these procedures may be best equipped to perform transoral flexible endoscopic therapy for ZD.

Preclinical training using an animal model is recommended to gain familiarity with the procedural nuances, such as the unique endoscopic view, gastroscope positioning and stability, and the correct identification of esophageal wall layers during dissection. An animal model using domestic pigs has been previously described in the literature.<sup>49</sup> Pigs are an ideal model for flexible endoscopic cricopharyngeal myotomy using the devices listed previously, due to their normal anatomic pharyngeal pouch that closely resembles a ZD.

## CONCLUSIONS

The principles in diagnosis and treatment of a ZD have remained largely unchanged for decades. Rigid transoral endoscopic therapy remains the most often used treatment modality, likely due to historical treatment and referral patterns; however, the continued

development of flexible endoscopic treatment allows select therapeutic endoscopists the opportunity to participate in the care of patients with symptomatic ZD. An abundance of available data on the flexible endoscopic approach has demonstrated equivalent efficacy when compared to the traditional open and rigid endoscopic approaches, with an acceptable adverse event profile. Nevertheless, the flexible endoscopic procedure demands considerable endoscopic skill and mastery of neck anatomy, as well as a thorough knowledge of the indications and contraindications of this approach.

## INTRODUCTION

In this chapter, we describe the evaluation, treatment, and subsequent long-term management for patients with benign esophageal strictures.

Patients with clinically significant esophageal strictures present with symptoms of dysphagia, typically first to solid foods. Symptoms may then progress in frequency and severity and some patients may develop dysphagia to liquids. Patients often modify their diets to avoid foods that lead to symptoms, and a thorough history is required to parse out the true severity of their symptoms. In the past, the most common etiology for esophageal strictures were peptic causes; however, the widespread use of proton pump inhibitor (PPI) therapy has markedly reduced the incidence of this etiology. Anastomotic and radiation-induced strictures are now the most common encountered overall, but the incidence of eosinophilic esophagitis associated strictures is increasing and being recognized more frequently in all age groups.

## INITIAL EVALUATION

The diagnosis of an esophageal stricture, both benign and malignant, commences with a clinical suspicion based on symptoms of esophageal dysphagia and is supported by elucidating a history of a known risk factor (Box 21.1). The maximal inner diameter of an esophageal stricture that will typically result in symptoms of dysphagia is 13 mm. Use of a validated dysphagia score allows for an objective measurement of symptoms and may be used to gauge response to treatment and inform research studies (Table 21.1).

When an esophageal stricture is suspected as the etiology of the dysphagia, the initial evaluation may begin with either a contrast esophagram or an upper endoscopy. In cases of mild, intermittent symptoms of dysphagia to certain foods (dysphagia

score of 1 or less), most gastroenterologists will proceed to endoscopy, as this pathway allows for both diagnosis and treatment with one procedure. In the presence of more significant dysphagia to most solid food (dysphagia score of 2 or above) or indeterminate symptoms, a barium swallow with optional 12.7 mm barium tablet should be considered, as it may provide additional information regarding the location, likely severity, and characteristics of the stricture. Knowledge of stricture characteristics is helpful when planning for the therapeutic endoscopic procedure, including appropriate endoscope selection (standard versus pediatric endoscope or bronchoscope) and assessing the potential need for fluoroscopy and adjunctive endoscopic accessories. For example, if the luminal diameter is less than 10 mm, but greater than 6 mm, a pediatric endoscope (5.9 mm) may be more likely to traverse the stricture endoscopically and would be advantageous to have on hand at the start of the procedure. Likewise, for narrower or more complex (long, angulated, or irregular) strictures, fluoroscopy may be required and preprocedure arrangements completed beforehand. An esophagram may also provide information on gross esophageal dysmotility, findings suggestive of achalasia, or the presence of proximal lesions such as esophageal bars or diverticuli that may be difficult to definitively visualize during endoscopy.

Strictures are typically classified as simple or complex. Simple strictures are focal (< 2 cm), straight, and easily traversed by an endoscope. These strictures are typically easily treated with standard dilation techniques.<sup>1</sup> Examples include Schatzki rings (Fig. 21.1), esophageal webs (Fig. 21.2), and some reflux-induced strictures (Fig. 21.3). Complex strictures are defined as angulated, multiple, or longer (> 2 cm), and typically cannot be traversed with a standard endoscope. Examples of typical complex strictures include those that may be the result of surgical anastomosis (Fig. 21.4), radiation therapy (Fig. 21.5), caustic ingestion (Fig. 21.6), ablative therapy, or neoplasm.

**Abstract**

In this chapter, we describe the evaluation, treatment, and subsequent long-term management for patients with benign esophageal strictures. Patients with clinically significant esophageal strictures present with symptoms of dysphagia, typically first to solid foods. Symptoms may then progress in frequency and severity and some patients may develop dysphagia to liquids. Patients often modify their diets to avoid foods that lead to symptoms and a thorough history is required to parse out the true severity of their symptoms. In the past, the most common etiology for esophageal strictures were peptic causes; however, the widespread use of proton pump inhibitor (PPI) therapy has markedly reduced the incidence of this etiology. Anastomotic and radiation induced strictures are now the most common types encountered overall, but the incidence of eosinophilic esophagitis associated strictures is increasing and being recognized more frequently in all age groups.

**Keywords**

stricture  
dilation  
dysphagia  
refractory  
recurrent

**BOX 21.1 Risk Factors for Esophageal Strictures**

- Chronic reflux symptoms/presence of a hiatal hernia
- History of esophageal sclerotherapy or photodynamic therapy
- Radiation related to treatment of head, neck, and lung cancer
- History of caustic ingestion
- History of esophageal/gastric cancer with an esophago-gastric anastomosis
- Prior ablative therapy in the esophagus for Barrett's or squamous dysplasia
- Nasogastric tube injury
- Eosinophilic esophagitis

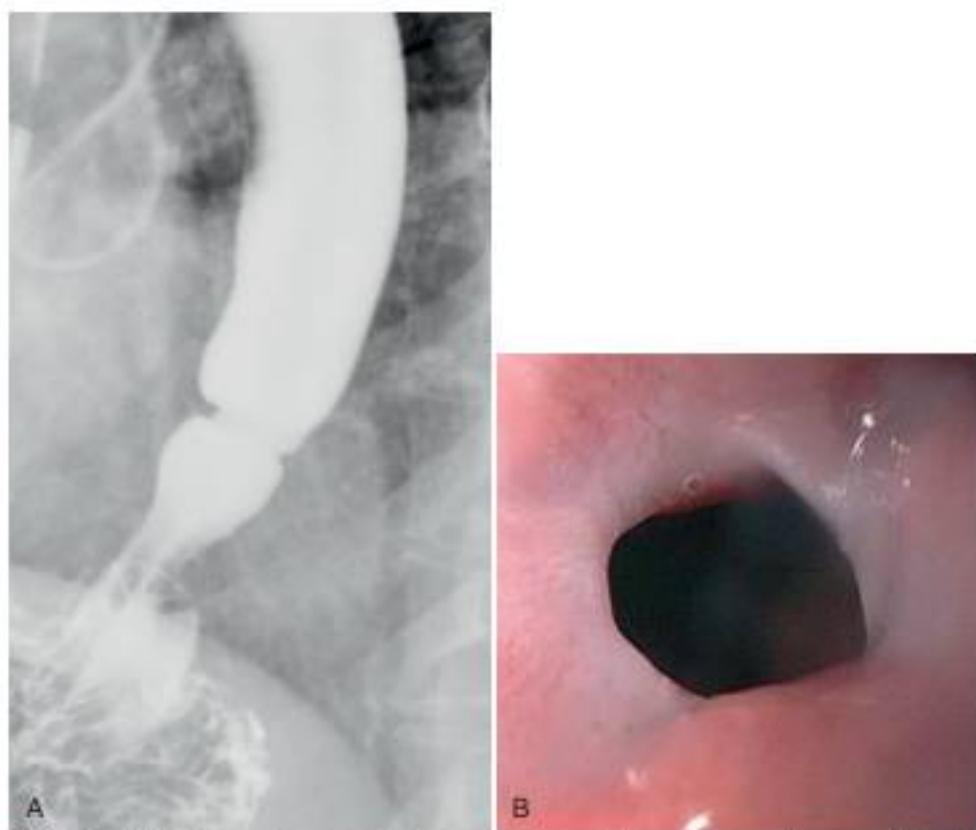

**TABLE 21.1 Dysphagia Score**

Score	Symptom Severity
0	Able to consume normal diet
1	Dysphagia with certain solid foods
2	Able to swallow semi-solid soft foods
3	Able to swallow liquids only
4	Unable to swallow saliva

Adapted from Sharma P, Kozarek R. Practice Parameters Committee of the American College of Gastroenterology. Role of esophageal stents in benign and malignant diseases. *Am J Gastroenterol* 105(2):258–273, 2010.

Treatment of esophageal inflammation with a PPI is recommended as inflammation may contribute to symptoms of dysphagia just as much as luminal strictures.<sup>2</sup> The main etiologies of inflammation in the esophagus are reflux, ischemia from prior surgery, caustic ingestion, and radiation-induced injury. If the stricture is due to inflammation from reflux, acid suppression is essential to promote a durable response to dilation and to prevent stricture recurrence. If a patient has persistent dysphagia despite normal upper endoscopy and a trial of PPIs, a dedicated esophagram with a barium tablet should be obtained to rule out a subtle luminal narrowing that may have been missed on endoscopy, and/or esophageal manometry to assess for motility disorders including achalasia. Moreover, extrinsic compression of the esophagus by mediastinal tumors, lymph nodes, or vascular structures may lead to dysphagia and may be more easily diagnosed by contrast esophagram than by upper endoscopy. Symptoms due to extrinsic compression are not typically amenable to long-term remediation by endoscopic dilation and may require endoprosthetic placement.

In some cases, history alone can be strongly suggestive of both the presence and etiology of an esophageal stricture, such as those patients with a prior history of caustic injury, radiation therapy, esophagectomy, or onset of symptoms following endoscopic therapy for Barrett's esophagus or squamous dysplasia. If symptoms arise within the early postoperative period following esophagectomy, anastomotic narrowing may be related to inflammation that will resolve with time or, alternatively, may be due

**FIG 21.1** **A**, Schatzki ring above hiatal hernia on prone single contrast esophagram. Note short vertical height of ring (seen as smooth, relatively symmetric area of ring-like narrowing) versus greater length of peptic strictures. **B**, Endoscopic appearance of typical Schatzki ring. (**A**, Courtesy of Marc S. Levine, MD.)

**FIG 21.2** **A**, Anterior cervical web on steep oblique (near lateral) view of pharyngoesophageal region and upper esophagus. Note thin, weblike indentation on anterior wall of upper cervical esophagus (cervical webs are typically seen as incomplete anterior structures and are less frequently circumferential). This patient also has a smooth, broad-based indentation on the posterior wall (the side the spine is on) secondary to mild cricopharyngeal dysfunction with incomplete opening of cricopharyngeus. **B**, Endoscopic appearance of esophageal web. Note the thin, smooth contour of the ring. (**A**, Courtesy of Marc S. Levine, MD.)

to early ischemia that would carry significant risk for wound dehiscence if aggressively dilated.

### PREPROCEDURE PLANNING

Preparation prior to upper endoscopy with the potential for dilation includes anticoagulation management, obtaining informed consent, sedation planning, selection of the equipment anticipated to be utilized, and determination of the appropriate venue for the procedure.

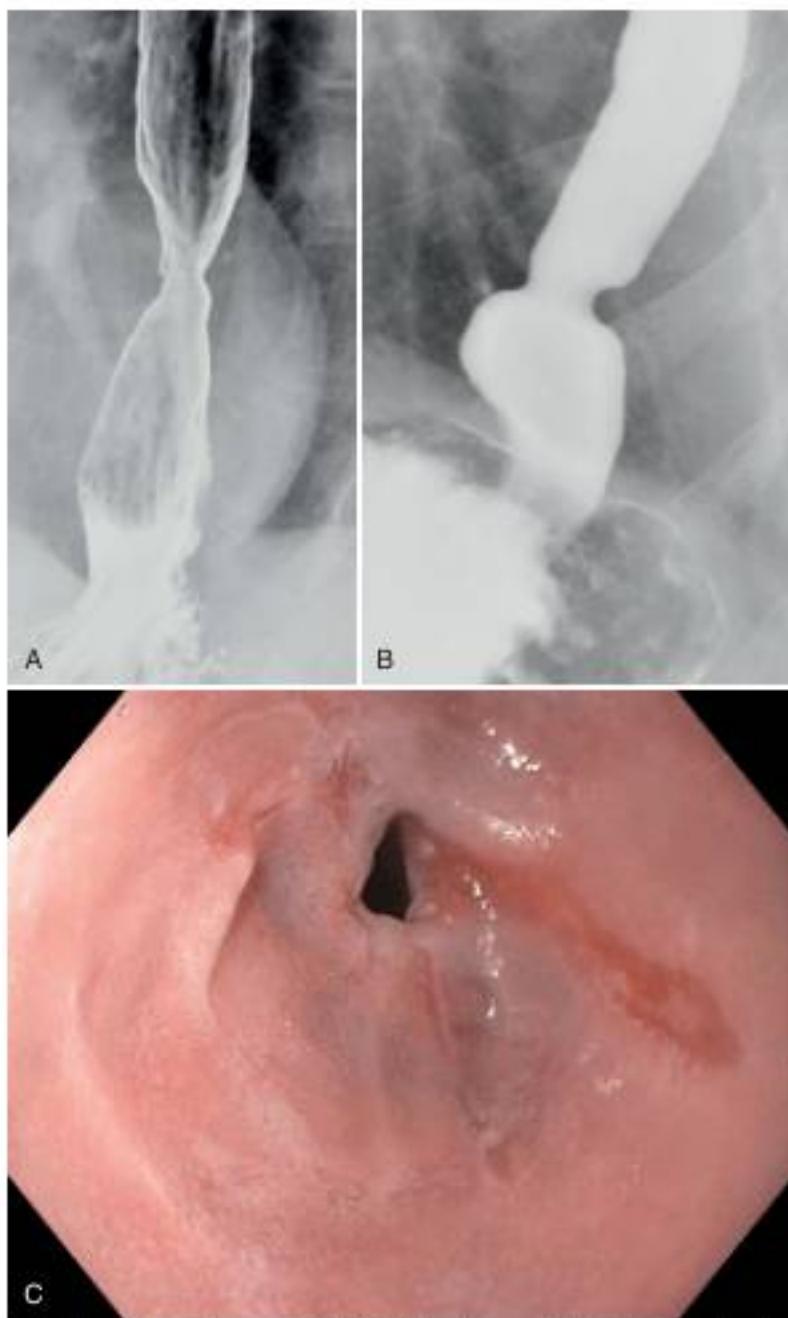

The American Society for Gastrointestinal Endoscopy (ASGE) recommendations on the management of antithrombotic agents for patients undergoing gastrointestinal (GI) endoscopic procedures rate the risk of bleeding related to dilation of benign esophageal strictures as low.<sup>3</sup> Despite the overall low risk of bleeding, the safety of dilation on anticoagulants remains unknown. Given the potential for bleeding at sites that are relatively difficult to access postdilation, dilation is categorized as a higher risk procedure as far as the use of antithrombotic agents. It is recommended that, when possible, anticoagulants and antiplatelet agents be held for sufficient time to allow for their effects to dissipate prior to dilation.<sup>3</sup>

The 2015 ASGE Standards of Practice committee guideline on the use of prophylactic antibiotics for GI endoscopy does

not recommend use of antibiotics prior to esophageal dilation.<sup>4</sup> Patients with vascular anomalies such as a prosthetic heart valve, history of endocarditis, or congenital defect repairs in the absence of prior vascular infection, do not require antibiotics. Despite esophageal dilation having a high rate of transient bacteremia (12% to 22%) in several prospective trials, the degree and duration of the transient bacteremia associated does not differ significantly from that resulting from routine activities such as brushing one's teeth.<sup>5</sup>

For most simple strictures, a standard upper endoscope without fluoroscopy is sufficient for a safe and successful dilation. For those patients with suspected complex esophageal strictures or high dysphagia scores (dysphagia score of 2 or above), having additional equipment available prior to the start of the procedure is recommended. Useful adjunctive equipment includes pediatric endoscope, bronchoscope, fluoroscopy, endoscopic retrograde cholangiopancreatography (ERCP) guidewires, and ERCP catheters for contrast injection. Whereas through-the-scope dilation balloons will not fit through the accessory channel of pediatric endoscopes, standard stainless-steel guidewires with flexible tips used for Savary wire-guided bougie dilation will pass.

In general, endotracheal intubation is not necessary prior to esophageal dilation. However, in the case of complete obstruction with a history raising the possibility of retained food or fluid in

**FIG 21.3** **A**, Peptic stricture above a small hiatal hernia on upright double contrast esophagram. Note relatively long segment of narrowing that has smooth, tapered proximal and distal margins, the classic radiographic findings of a peptic stricture. **B**, Short peptic stricture in distal esophagus above hiatal hernia on prone single contrast esophagram. Note short segment of smooth, asymmetric narrowing with tapered margins in distal esophagus. **C**, Endoscopic appearance of classic short peptic stricture. Note the presence of active esophagitis. (**A** and **B**, Courtesy of Marc S. Levine, MD.)

the esophagus, endotracheal intubation may be prudent. Most patients with simple strictures can be safely dilated in the ambulatory setting.

### RISKS/ADVERSE EVENTS

The overall rate of adverse events of esophageal dilation is estimated to be between 0.1% and 0.4%.<sup>1,5,6</sup> Perforation and

bleeding are the most common adverse events with lower incidences for pain, aspiration, and infection.

Risk factors for adverse events related to dilation include the presence of a complex stricture, prior radiation therapy, caustic ingestion, esophageal pseudodiverticulum, and possibly chronic steroid use and surgically altered anatomy.<sup>7</sup> Although there was initially concern for an increased risk for perforation in patients with eosinophilic esophagitis (EoE), more recent data (2010)

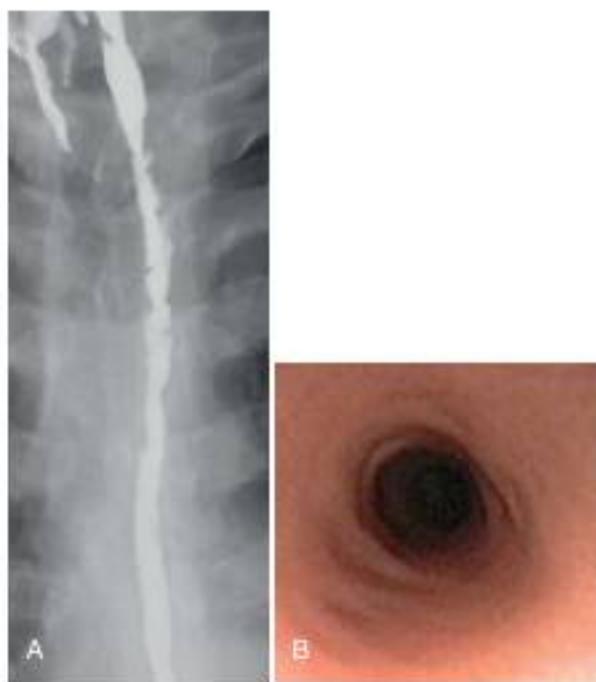

**FIG 21.4** **A**, This patient has had an esophagogastrectomy and gastric pull-through with an end-to-end esophagogastric anastomosis in the upper thorax below the thoracic inlet on upright esophagram. There is a benign anastomotic stricture seen as a short segment of smooth, symmetric narrowing without significant obstruction to flow of barium (though this patient had solid food dysphagia). **B**, Endoscopic appearance of esophagogastric anastomotic stricture. Note the presence of the surgical staple at the anastomosis. (**A**, Courtesy of Marc S. Levine, MD.)

**FIG 21.5** **A**, Radiation stricture in upper thoracic esophagus at level of aortic arch on prone single contrast esophagram. Note smooth contour and tapered margins of stricture, findings characteristic of scarring from radiation. **B**, Endoscopic appearance of radiation stricture with active inflammation. Note the long segment of stenosis that correlates with radiation therapy. (**A**, Courtesy of Marc S. Levine, MD.)

does not appear to support this.<sup>8</sup> Despite the absence of an increased risk of perforation in patients with EoE, the risk of postdilation pain is greater in these patients and the patient and physician should be aware of this.

Likely risk factors for clinically significant bleeding following dilation are radiation induced strictures and complex strictures.

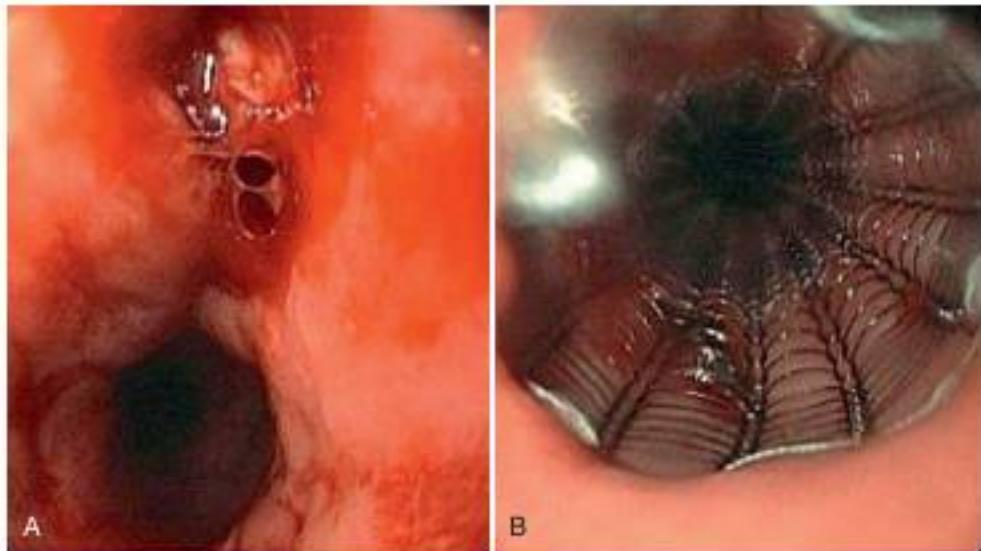

**FIG 21.6** **A**, Lye stricture seen as long area of irregular and marked narrowing in thoracic esophagus on upright single contrast esophagram. Note irregularity of contour, most likely secondary to multiple intramural dissections. **B**, Endoscopic appearance of chronic stricture due to prior lye ingestion. Note the long, significantly narrowed lumen. (**A**, Courtesy of Marc S. Levine, MD.)

Most mucosal tears will stop bleeding spontaneously; however, if significant bleeding requiring transfusion is observed or suspected after the procedure, a repeat endoscopy to evaluate for utility of endoscopic therapy should be considered. Bleeding following dilation of complex strictures that cannot be traversed with an adult endoscope may be more challenging, or even impossible to treat endoscopically due to lack of access to the bleeding site. Pediatric endoscopes may be useful in this setting to assess and treat. Some patients may have a gastrostomy that would make retrograde endoscopy another potential approach for hemostasis.

Although a full discussion of the management of dilation-related esophageal perforation is beyond the scope of this chapter, it is critical to be aware of the signs of, and initial evaluation of, a suspected perforation. Early recognition and steps to avoid gross mediastinal contamination are of paramount importance and vital to reducing the risk of death. In 390 patients with acute esophageal perforation, when comparing the mortality rate of those who received care either within 24 hours or those treated after 24 hours, it was demonstrated that the mortality rate was twice as high (27% vs. 14%) in those treated after 24 hours.<sup>9</sup> Perforations may occur in the cervical, intrathoracic, or subdiaphragmatic regions following dilation. Clinical manifestations of perforation include pain in the neck, ear, chest, or abdomen, odynophagia, dysphagia, fever, tachycardia, and the finding of subcutaneous emphysema. Lack of any of these signs and symptoms does not definitely exclude perforation; clinical suspicion plays an important role to lead to further investigation and early diagnosis (Fig. 21.7).

If there is any question of perforation, the patient should be kept NPO until either the pain subsides or studies are done to exclude perforation and the concern for perforation is resolved. Broad-spectrum antibiotics should be instituted and a nasogastric (NG) tube placed for decompression of the stomach to minimize reflux of contents into any potential esophageal defect. The NG tube may require additional modalities (e.g., fluoroscopy) to ensure that it is intragastric and not exiting through a potential site of perforation. Although a chest x-ray is frequently the initial

**FIG 21.7** **A** and **B**, Suspected esophageal perforation of a radiation stricture following Savary dilation. Note the air bubbles and appearance of muscle tissue at site of the rent. Due to concern for a leak, a fully covered esophageal stent was deployed during the procedure.

test ordered when there is concern for perforation, extraluminal air alone is not associated with significant morbidity, except in cases of significant pneumothorax. The major concern is leakage of fluid and particulate matter into the mediastinum. Assuming the perforation was not directly visualized during the endoscopy, the initial study should be a water-soluble esophagram to evaluate for extravasation of contrast into the mediastinum. If demonstrating a leak, a computed tomography scan should be considered to evaluate for fluid collections that may require separate drainage; a surgical consultation should be obtained.

Often mature anastomotic strictures or those resulting from radiation are fibrotic, and tissue planes are obliterated such that free uncontained perforations are less common even in the setting of a significant esophageal wall defect. Contained perforations (Fig. 21.8) can often be managed conservatively; surgical teams should be consulted to assist as patients with esophageal perforation may become septic and unstable early in the course.

Attempts at closure of the esophageal defect with hemoclips or an over-the-scope (OTS) clip can be considered and is more likely to be successful when the perforation is within the chest and not at or extending across the gastroesophageal (GE) junction. If the stricture is relatively fibrotic, closure with clips can be challenging due to a lack of flexibility of the esophageal wall. If an OTS clip is used, one should use caution not to compromise the lumen of the esophagus, which would effectively make matters significantly worse. Endoscopic treatment options also include bridging the defect with a fully covered, self-expanding stent. Esophageal stents have been shown to be relatively effective in managing esophageal perforations in several case series and prospective studies<sup>10–12</sup>; however, the Practice Parameters Committee of the American College of Gastroenterology felt the quality of evidence to be low and strength of recommendation for their use weak.<sup>13</sup> If endoscopic closure is attempted, efforts

to close the leak to limit mediastinal contamination should be performed expeditiously. An esophagram to ensure effective diversion around the defect following stent placement should be obtained. Fully covered stents have a relatively high rate of migration and a chest x-ray may be obtained to ensure lack of migration for the first few days or if concern for displacement occurs. Repeat endoscopy to remove the covered stent in 4 to 6 weeks should again be typically followed by an esophagram to ensure remediation of the defect.

## INITIAL INSPECTION

Relative contraindications to dilation include recent esophageal perforation and malignant appearing strictures. If, upon initial inspection of an esophageal stricture, an underlying malignancy or infectious etiology is suspected, the lesion should be biopsied prior to aggressive therapeutic intervention. Tissue sampling should also be considered if there are findings consistent with eosinophilic esophagitis, concurrent inflammation, or ischemia. As biopsies are almost always mucosal with very rare exception, biopsy prior to dilation is considered safe.

## TYPES OF DILATORS

There are three primary types of dilators used for esophageal dilation: (1) metal filled rubber bougies with either a blunt (Hurst) or tapered tip (Maloney) used without a guidewire, (2) polyvinyl wire-guided bougies, and (3) through-the-scope (TTS) balloon dilators. With the exception of the indication of patient self-dilation, liquid metal filled bougies have been largely supplanted by wire-guided and balloon dilators. Wire-guided bougies range in size from 5 mm to 20 mm (15 Fr to 60 Fr) and dilation balloons are available in a comparable range of sizes (Table 21.2).

### Selection of Dilating Devices: Balloons Versus Bougies

Stricture dilation can be achieved with either a rigid, wire-guided bougie or a balloon dilator, either wire-guided or without a wire. These dilation methods differ in their manner of delivery of dilating force to the stricture. Wire-guided bougies are mechanical dilators that exert both longitudinal and radial shear forces. Theoretically the radial dilating force increases within the stricture as the tapered dilator is advanced. Balloon dilators deliver nearly pure radial shear force over the length of the stricture with significantly less longitudinally shear stress.<sup>14,15</sup> Despite mechanistic differences between the two, there has been no data to suggest superiority of either type of dilator in regard to complication rates or significant superiority for symptomatic relief of dysphagia.<sup>1,16–19</sup> In a study comparing the perforation rates

**FIG 21.8** Esophagram of a contained esophageal perforation following dilation of a radiation induced stricture. Note the limited extravasation of contrast due to extensive fibrosis.

**TABLE 21.2 Esophageal Dilators**

Mercury- or tungsten filled bougies	Maloney (tapered tip) Hurst (blunt tip)

between Maloney, balloon and wire-guided bougie dilation of complex esophageal strictures, blind (non-wire-guided) passage of a Maloney dilator was associated with increased risk of perforation when compared to the other dilator types, despite endoscopic evaluation immediately before Maloney dilation in three of the four perforations reported.<sup>2</sup> We therefore advocate the use of wire-guided or balloon dilators for all esophageal strictures, with the notable exception of self-dilation for recurrent esophageal strictures in carefully selected patients.

Selection of a type of dilator should then be based on the comfort level and experience of the operator, although there are clinical scenarios where we advocate preferential use of one type of dilator over the other. The ability to have direct visualization endoscopically and fluoroscopically combined with lack of longitudinal shear stress make balloons preferable for dilation of anastomotic strictures in the immediate postoperative period, as well as for selected caustic and radiation strictures, due to the potential risk for proximal perforation (above the stricture) with the longitudinal force that bougie dilators exert in difficult to dilate strictures. In cases in which the standard endoscope, or pediatric endoscope, cannot pass beyond the stricture, or if visualization beyond the stricture is not clear, we advocate for the use of fluoroscopy with passage of a guidewire into the gastric lumen. Bougies are preferred in some cases as they are more likely to effect dilation to the stated diameter of the dilator in scirrhous strictures. This is demonstrated in cases where increasing balloon diameter may not correlate with the maximal diameter obtained within the stricture despite appropriate pressure registered on the inflation device, which is observed as a "waist" on the balloon when under fluoroscopy with contrast (Fig. 21.9). In addition, balloon dilators may not dilate fully in a 360-degree

circumferential manner. Wire-guided dilators may also be easier to use for proximal strictures, cricopharyngeal bars, and webs, as endoscope position above the upper esophageal sphincter during dilation may not be well tolerated. Finally, bougie dilators are reusable and therefore may be more cost-effective in the long run, though local costs for reprocessing are variable.

Fluoroscopy is not needed to safely perform most esophageal dilations as most are simple strictures and may be traversed. In a study of over 300 patients having wire-guided bougienage, fluoroscopy was only required in 8% of cases.<sup>23</sup>

## DILATION

One of the major tenets for a safe and successful dilation is both proximal and distal localization and control of the stricture (i.e., the endoscopist should have knowledge of the proximal and distal extents, as well as assurance that the dilator will effectively be able to engage the full length of the stricture). For bougie dilation, a guidewire is first passed through the residual lumen of the stricture distally via the accessory channel of the endoscope under direct endoscopic and/or fluoroscopic visualization. The endoscope is then withdrawn over the guidewire, which is maintained stable in a constant wire position. Standard guidewires have distance markers marking 20 cm increments; the inserted length of guidewire should be confirmed after withdrawal of the endoscope to confirm that the wire was maintained through the stricture in a stable position.

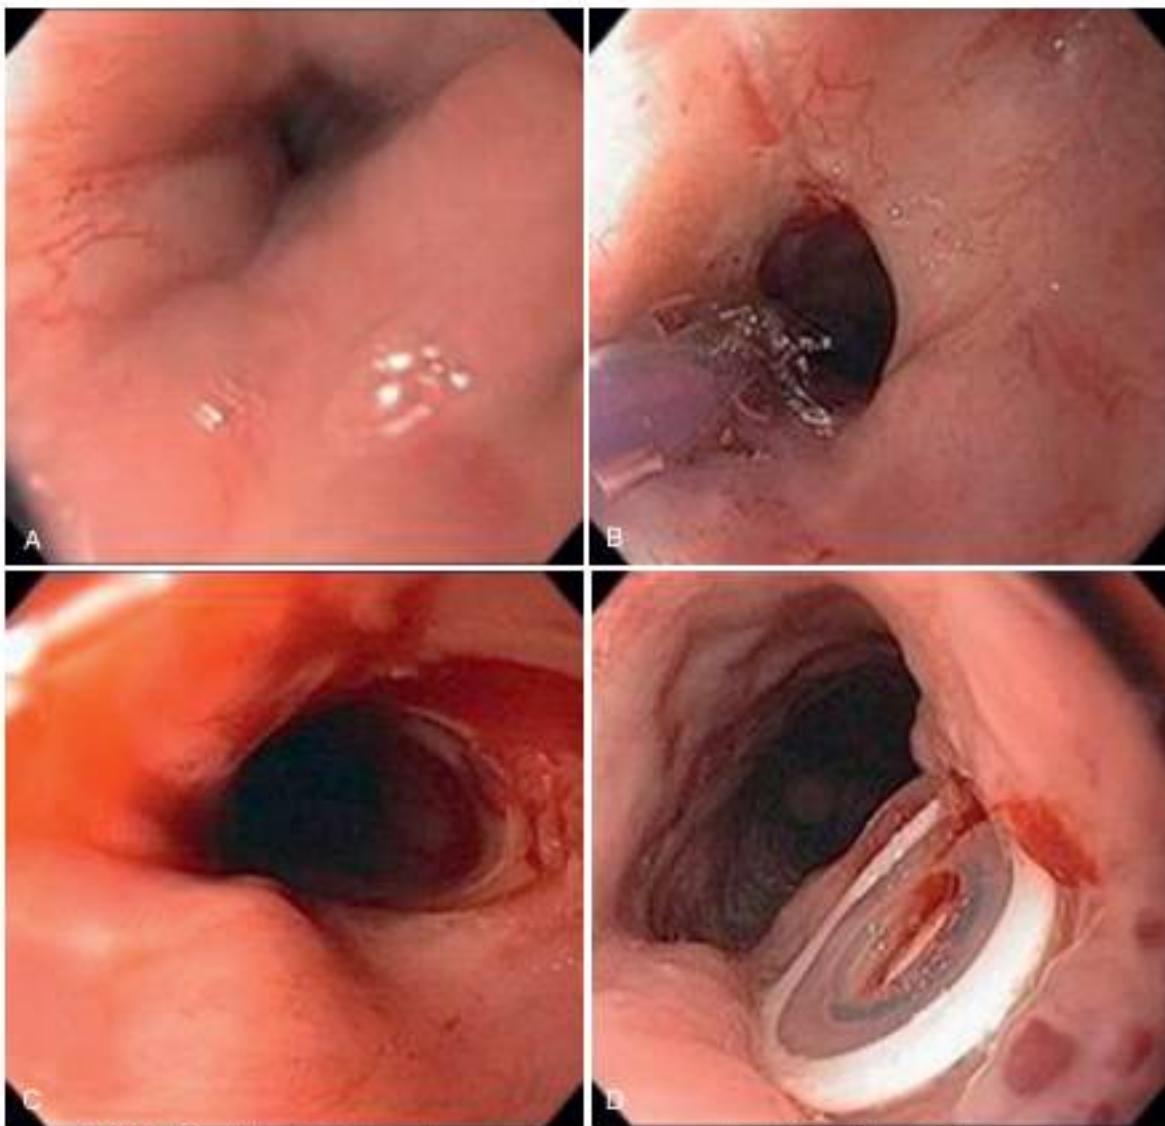

A general guide for safely dilating esophageal strictures with a rigid bougie dilator, known as the rule of threes, dictates that once moderate resistance is felt with passage of the dilator across the stricture, the diameter of the dilator is then increased by no more than two dilators of 1 mm ( $\equiv$  3-Fr) increments. Although a common practice, there have not been prospective studies validating that the rule of three reduces the risk of perforation. In fact, a 2017 study retrospectively examined adverse events when they were nonadherent to the rule of three and found no increased risk of perforation or other adverse events.<sup>24</sup> In a study of over 400 patients with single session dilation in which either multiple bougie dilators or a single >45-Fr dilator was used, there was only one perforation.<sup>25</sup> If larger diameters are desired, sequential repeat dilation at intervals ranging from 24 hours to 4 weeks may be efficacious and safe to achieve adequate dilation. It is generally safe to dilate a Schatzki ring directly to 18 mm with a single rigid dilator.

As resistance will not be transmitted to the operator, the rule of three does not apply with balloon dilation. The maximal expansion planned for a session should be reasonable for the suspected etiology and starting size of the stricture. In patients who are undergoing repeat dilations, it is reasonable to dilate to the maximal diameter plus one millimeter from the prior session if safely done in the previous few weeks, even if the diameter has decreased significantly. Once a size is selected, the balloon is typically inflated and held in place for 30 to 60 seconds, although the exact duration and number of dilations has not been validated. Water or contrast, and not air, should be used for inflation, as liquids are less compressible than air.

It is important to assess the response to dilation intraprocedurally. Without evidence of trauma, meaningful durable dilation is unlikely. A mucosal rent is a sign of satisfactory dilation and remediation of a mucosal-based stricture (Fig. 21.10). Visual inspection may also raise awareness of a perforation prompting further evaluation.

**FIG 21.9** Fluoroscopic image of a through-the-scope balloon dilation of an esophageal stricture with persistent waist (arrow). Note that without fluoroscopy, the postdilation diameter of the stricture may be less than anticipated based on diameter of the controlled radial expansion (CRE) balloon.

**FIG 21.10** Combined radiation and anastomotic stricture in a patient after radiation and laryngectomy with tracheoesophageal voice prosthesis. Note the stricture **A**, before, **B**, during, and **C**, immediately after dilation. Note the presence of a mucosal rent after dilation suggestive of a satisfactory dilation. **D**, Care must be taken to avoid displacement of the prosthesis during endoscopic therapy.

### Foreign Body Removal

Protruding surgical staples or visible suture at anastomotic strictures can often be visualized prior to or after successful dilation. It has been suggested that the presence of either may impair stricture remediation by contributing to inflammation and scarring and removal with forceps or endoscopic scissors is speculated to decrease stricture recurrence.<sup>1</sup> In a study by Mendelson et al (2015), removal of staples or sutures at surgical anastomotic strictures trended, but did not reach statistical significance, toward decreasing time to initial patency. There was additionally no effect on the total number of dilations required to achieve clinical response.<sup>22</sup> Despite this common albeit low-risk practice, no studies have conclusively shown removal of surgical staples or sutures to alter the clinical course, and the decision to do so is at the discretion of the endoscopist.

### POSTDILATION FOLLOW-UP

The goal of treatment is to reduce or eliminate symptoms of dysphagia to allow sufficient and gratifying oral nutrition. Depending on the etiology, length, and complexity of a stricture, completely ameliorating symptoms is not always possible. However, if a systematic approach is followed, the likelihood of success is increased. The patient should be aware that symptomatic relief is often possible but will require active involvement on their part. This involves following dietary and medication recommendations, understanding the potential for frequent dilations every 1 to 2 weeks initially, with decreasing intervals pending response, and acceptance of an increasing level of risk for complications if standard therapies are ineffective and alternative techniques are employed. The risks of therapeutic interventions should be considered prior to every intervention and weighed

against the response already achieved by the patient and the overall goals of therapy.

Whereas some characteristics, including complexity of stricture and etiology, may portend a lower response rate to mechanical dilation, ultimately there is no validated method to accurately *a priori* predict response to dilation. As such, a trial of mechanical dilation remains the mainstay of initial therapy for the management of benign esophageal strictures. The need for repeat dilation will depend partly on symptomatic response to therapy, as well as anticipated need to return based on suspected etiology of the stricture, diameter of prior dilation, presence of active inflammation, and postdilation appearance. Symptomatic relief is generally not achieved until stricture remediation to at least a diameter of 13 mm. This may not always be the case and routinely pursuing a dilation target size in the face of symptomatic relief reported by the patient is not advised. Conversely, if a patient continues to have significant dysphagia despite successful stricture remediation to a diameter greater than 15 mm, other confounding etiologies, such as dysmotility related to neuromuscular damage from radiation, surgical intervention, prior cerebrovascular accident, or connective tissue disorders, should be considered. A barium esophagram may be informative in these instances, often in conjunction with a speech pathology evaluation.

Presence of inflammation will hinder, if not prevent, successful remediation of an esophageal stricture. Adequate acid suppression is therefore critical in successful remediation of a stricture. In a study by Patterson et al (1983) prior to the widespread use of PPI therapy, 43% of patients with benign strictures responded to only one session of dilation.<sup>23</sup> Now with effective acid suppression, only 30% of patients with peptic strictures will require repeat dilations in 1 year, most commonly in patients with hiatal hernias or persistent symptomatic heartburn following dilation.<sup>24</sup> In a study of 140 patients (57% postsurgical, 26% peptic, 9% caustic, 8% other), adequate response to mechanical dilation to a diameter of 14 mm was achieved in 94% of patients. The authors found that peptic strictures needed one to three dilation sessions, whereas patients with postsurgical or caustic strictures required more dilations, with a maximum of five sessions in 95% of patients.<sup>25</sup> In this study, only 25% to 30% of patients with simple strictures required any repeat dilation.

If a simple stricture, such as a Schatzki ring, web, or peptic stricture, is dilated to a diameter expected to relieve symptoms of dysphagia, it is then reasonable to have the patient return if, or when, symptoms of dysphagia recur. If they have recurrent symptoms within a short period of time (< 6 months), compliance with a PPI should be discussed prior to repeat endoscopy.

If the underlying mechanism of injury resulted from deep ulceration or chronic inflammation, such as caustic or radiation injury, it should be anticipated that it will require multiple dilation sessions and possibly adjunctive therapy in order to achieve adequate clinical response.<sup>15,22</sup> Rana et al (2015) evaluated the relationship between wall thickness, depth of involvement, and the need for multiple dilations using endoscopic ultrasound.<sup>26</sup> They demonstrated that the depth of involvement, specifically deeper lesions involving the muscularis propria, and not the thickness of the esophageal wall, predicted a need for more dilation sessions.<sup>26</sup> This is congruent with data that caustic and radiation-induced strictures, which may involve the submucosa or in some instances be transmural, require more sessions. Although of interest, the use of endoscopic ultrasound for evaluation of benign esophageal strictures is not currently recommended as it does not change standard management, specifically,

a trial of serial mechanical dilation. However, knowing the likely inciting injury may have caused deeper injury (i.e., caustic, radiation therapy) can be useful for early patient discussions regarding the likely need for repeated dilation and for tempering expectations as to the degree at which resolution of symptoms will occur. Anastomotic strictures following surgery for esophageal or head and neck cancer are also typically more difficult to remediate and will often require multiple dilations for sustained clinical response.<sup>15,27-29</sup> Strictures related to cap-assisted endoscopic mucosal resection are more likely to form with an increasing percentage of circumferential treatment area. Fortunately, these strictures often respond to one treatment with a dilator.<sup>30</sup>

## REFRACTORY OR RECURRENT STRICTURES

It can often take several sessions of dilation before a satisfactory long-term response is seen. Definitions for both refractory and recurrent strictures have been developed: a refractory esophageal stricture is defined as a stricture that could not be successfully remediated to a diameter of 14 mm over five sessions at 2-week intervals. A recurrent stricture is a stricture that does not maintain a satisfactory luminal diameter for 4 weeks once the target diameter of 14 mm has been achieved.<sup>31</sup> Exceptions to either of these definitions are patients with inflammatory strictures or underlying neuromuscular dysfunction as a result of surgery or radiation. Inflammatory strictures are not expected to respond significantly to dilation until the underlying inflammation has been treated. Furthermore, patients with underlying neuromuscular dysfunction can have continued dysphagia despite achieving a luminal diameter of greater than 14 mm. In these patients, it is reasonable to remediate the stricture to 14 mm and evaluate for clinical response. If symptoms of dysphagia persist, motility studies could be considered; however, further dilation to greater luminal diameters would likely have minimal clinical response coupled with an increased risk of complication. Other considerations for continued dysphagia include poor mastication of food due to neuromuscular dysfunction or ill-fitting dentures related to accompanying weight loss.

When complete resolution of dysphagia is not possible through stricture remediation, a consultation with a speech pathologist coupled with a combination of a modified diet and deliberate chewing will often allow the patient to maintain normal daily and social function without succumbing to complications of additional dilation, endoprosthetic, or surgical intervention. There should be frequent communication with the patient regarding symptomatic improvement and the goals of therapy, especially in the setting of multiple comorbidities.

## ADJUNCTIVE THERAPIES

Once a stricture has been deemed to be either refractory or recurrent, successful remediation, if obtainable, will typically require adjunctive techniques. This section includes intralesional steroid injection, incisional therapy, and transient placement of an endoprosthetic.

### Intralesional Steroid Injection

Intralesional steroid injection is thought to reduce remodeling and fibrosis following mechanical dilation to prevent or reduce stricture recurrence. Literature supporting the efficacy of steroid injection with concurrent dilation for refractory or recurrent strictures is not definitive with variable results reported. A

prospective, randomized, double-blind, placebo-controlled trial evaluated the effect of intralesional steroid injection followed by balloon dilation of peptic strictures and showed that 2 out of 15 patients treated with steroids compared with 9 out of 15 patients with sham therapy required repeat dilation in one year.<sup>32</sup> The efficacy of intralesional steroid injection has been more variable for other types of benign esophageal strictures. For example, delayed radiation-induced strictures are less likely to respond to steroid injection because these strictures are due to extensive fibrosis.<sup>33</sup>

A multicenter, double-blind trial tested whether untreated cervical anastomotic strictures following esophagectomy were more effectively treated with intralesional steroid injection combined with bougie dilation to 16 mm than placebo with dilation. In this study, there was no statistical difference in the dysphagia-free interval up to 6 months, complications or quality of life. Although this study saw no reduction in repeat dilations or prolongation of dysphagia-free intervals, it should be noted that these were treatment naïve patients and not in patients with refractory strictures for which adjunctive steroid injection is normally considered.<sup>34</sup> Conversely, benefits were seen in a nonrandomized study of 19 patients with refractory anastomotic strictures following esophagectomy with a significant decrease in the periodic dilation index following steroid injection.<sup>35</sup> A positive benefit was also seen in a retrospective study of 30 patients with subtotal esophagectomy complicated by an anastomotic stricture who were either treated with intralesional steroid injection and endoscopic balloon dilation (10 patients) or balloon dilation alone (20 patients). The patients in the steroid group required less repeat endoscopies with balloon dilation (2.5 [1-6] vs. 4.5 [1-20]) and had a significantly shorter interval between first treatment and resolution of stenosis (58.5 days [0-142 days] vs. 94.5 days [0-518 days]).<sup>36</sup>

In a study of 14 patients with caustic strictures, intralesional steroid injection combined with dilation significantly decreased the interval between dilations as compared with prior dilation regimen alone.<sup>37</sup> In one randomized study of only 14 patients comparing steroid versus saline injection,<sup>38</sup> there was improvement in maximal diameter reached, but not in dysphagia score or frequency of dilation. In another study of 29 patients with caustic strictures, there was again a decrease in the periodic dilation index and associated significant improvement in the dysphagia score.<sup>39</sup>

The dose and steroid used for treatment is also variable in practice. Triamcinolone (Kenalog, Bristol-Myers Squibb Company, Princeton, NJ) is the most commonly used, with four to eight circumferential injections of 0.5 to 1.0 mL/injection for a total dose of 40 to 80 mg. There is also variable practice regarding injection before or after dilation. Injection before dilation allows adequate submucosal delivery with potential for both loss due to compression and for deeper and more extensive tissue dispersion during dilation. Injection after dilation can make injection difficult, with steroid leakage at mucosal tears and reduced visibility due to active oozing, although it does allow for injection within longer complex strictures that are not accessible prior to dilation. It is our preference to inject 4 × 10 mg from the proximal aspect into the stricture prior to dilation for focal strictures and following dilation for longer strictures.

In summary, the likelihood of response varies depending on the etiology of the stricture. Given the low risk of steroid injection and the increased risks of alternative approaches following failed mechanical dilation, we recommend a trial of intralesional steroid

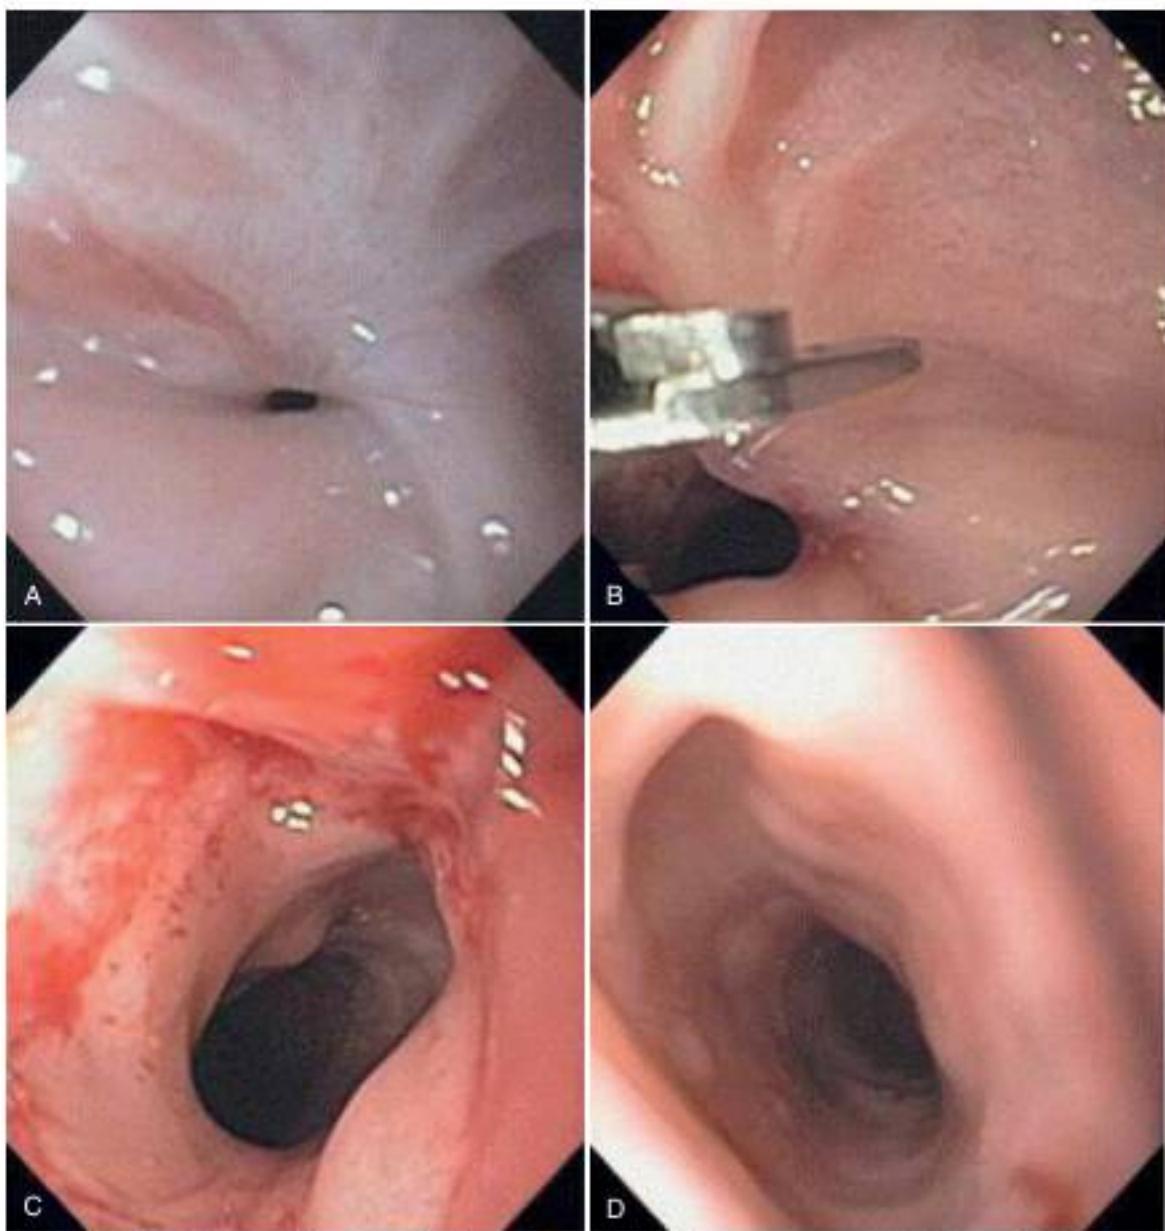

injection combined with dilation for strictures that fail to respond to dilation or those that rapidly return to near predilation diameter. The practice is considered safe and low risk with few reports of adverse events, such as increased Candida esophagitis.<sup>34</sup> Inflammation at the stricture should be managed and reduced prior to considering adjunctive steroid therapy. If after three sessions, there is no significant improvement in either the response of dilation or frequency of dilations required, it is unlikely to provide any additional benefit and other adjunctive methods should be employed.

### Endoscopic Incisional Therapy

Endoscopic incisional therapy is a technique of making 8 to 12 radial incisions of the intraluminal stricture longitudinally oriented to the esophageal lumen. The incised stricture is then either dilated with a bougie or balloon dilator or, in some instances, the tissue between cuts excised off circumferentially with a needle knife. No studies have shown superiority of one approach over the other. The method of incision has been described using a number of tools including endoscopic scissors<sup>40</sup> (Fig. 21.11) and needle knives<sup>41</sup> either with or without an insulated tip.

Evidence best supports incisional therapy in patients with short segment (< 1 cm) strictures due to either refractory Schatzki rings or anastomotic strictures.<sup>42</sup> A study comparing incisional therapy to mechanical dilation as primary therapy for anastomotic strictures in treatment naïve patients was shown to have a similar safety and response to mechanical dilation, although not a superior response rate at 6 months when compared to dilation alone.<sup>43</sup> In another prospective study, 24 patients underwent incisional therapy as primary treatment; at 24 months follow-up, 21 out of 24 patients had no symptoms of dysphagia after having received only one treatment session. Of those that responded, 21 of 22 patients had a stricture less than 1 cm, whereas only one out of three patients with strictures greater than 1 cm responded. No significant bleeding or perforations were reported.<sup>44</sup> In a study of 20 patients with anastomotic strictures who failed repeated bougie dilation, incisional therapy with electrocautery was performed. All the patients with strictures of less than 1 cm were dysphagia free at 1 year (12/20). Most of the remaining patients with longer strictures (1.5 to 5 cm) responded to therapy but required a mean of three additional treatment sessions. There were no immediate or delayed complications.<sup>45</sup> A retrospective study by Muto et al (2012)<sup>46</sup> described the clinical response of the "radial incision and cutting (RIC)" method of incisional therapy for 54 patients with refractory anastomotic esophageal strictures compared with continued management with repeat balloon dilation. Approximately 63% of patients were able to eat solids after 12 months compared with only 20% of patients treated with balloon dilation alone. In another study of nine patients with anastomotic strictures that did not respond to mechanical dilation, needle-knife incision reduced dysphagia symptoms in eight out of nine, with a reduced need for endoscopic dilation during follow-up 90 to 420 days compared with a mean of 13 days prior. No complications occurred.<sup>47</sup>

Although studies have not shown significantly higher complication rates of incisional therapy in expert hands, we recommend that endoscopic incisional therapy be reserved for management of refractory or recurrent strictures that have already failed dilation with adjunct intralesional steroid injection and that it be performed by experienced endoscopists. Strictures less than 1 cm in diameter are most likely to have a positive response to incisional therapy.

**FIG 21.11** Incisional therapy with endoscopic scissors. **A**, A severe esophageal stricture refractory to bougie dilation. The stricture is treated by **B**, cutting the fibrotic stricture with endoscopic scissors, followed by **C**, bougie dilation. **D**, At 4-week follow-up, the appearance was satisfactory with good clinical response. (From Beilstein MC, Kochman ML: Endoscopic incision of a refractory esophageal stricture: novel management with an endoscopic scissors. *Gastrointest Endosc* 61[4]:623–625, 2005.)

### Endoprosthetics

Once a benign refractory esophageal stricture fails to respond to dilation with adjunctive steroid injection and/or incisional therapy, endoprosthetic placement should be considered prior to referral to surgery or declaring a failure of remediation. Available stents used for treatment of benign esophageal strictures include self-expanding fully covered metal stents (SEMS), plastic stents (SEPS), and biodegradable stents (BDS). Uncovered metal stents should never be used for benign strictures and, despite reports of partially covered stents being used to prevent migration, we do not recommend their use due to concern that the uncovered portions of the stents will embed in the esophageal wall.

Common adverse events related to stent placement include migration, mediastinal pain, nausea, and vomiting. Nausea may be severe, and patients should be warned prior to placement, with a plan for antiemetics and pain control as needed following placement, though this is less frequent than for patients with malignant esophageal obstruction. Location of the stricture is also important as patients with very proximal strictures can often feel a foreign body sensation in addition to pain following placement. Esophageal stents also increase the risk for aspiration, especially if they cross the GE junction. Long-term complications include potential fistula formation and tissue overgrowth at the ends of the stent, creating partial obstruction and making removal challenging. Finally, symptoms of dysphagia can recur following

stent removal, as stent placement often does not treat the underlying etiology of the stricture.

A retrospective study by Repici et al (2016)<sup>47</sup> studied 70 consecutive patients at two tertiary institutions over a 15-year span to evaluate the outcomes of patients with benign esophageal strictures refractory to dilation treated with esophageal endoprosthetics. Patients were treated either with serial dilations or with dilations and esophageal stent placement (SEMS, SEPS, or BDS). Clinical success was defined as no need for additional endoscopic procedures for 6 months after endoprosthetic removal or from the time of the last dilation. In this study, only one out of three patients (approximately 31%) with refractory benign esophageal strictures (RBES) achieved clinical success. It was concluded that endoprosthetics failed to improve clinical response rates and were of limited value.

A European multicenter randomized study of 66 patients with RBES compared biodegradable endoprosthetics with ongoing dilation. There was a longer time to recurrent dysphagia (95 days vs. 30 days), as well as improved quality of life, with placement of an endoprosthesis. Complications of stent placement included two perforations and two fistulas. Hirdes et al (2012) used sequential biodegradable stents in patients with refractory strictures and demonstrated a similar clinical response rate with 25% dysphagia free at 6 months and with major complications occurring in 29%.<sup>48</sup>

Finally, a recent systematic review and meta-analysis by Fuccio et al (2016)<sup>49</sup> combined 18 studies (444 patients) and found a slightly higher rate of response, with stent placement effective in approximately 40% of patients with RBES. There were no differences in response rate, migration rate (28.6%), or adverse events (20.6%) when comparing SEMS, SEPS, and BDS.

Mortality rates associated with treating RBES ranged from 1.7% to 2.8% in studies with 168 and 70 patients, respectively.<sup>50,51</sup> Although relatively high, it was noted by Siersema (2016) that these rates were similar to that of esophagectomy. Additional studies are required to determine which stricture characteristics are most likely to durably respond to dilation therapy. Furthermore, it is anticipated that improvements in endoprosthetics to achieve a balance between sufficient radial force to prevent migration and characteristics to decrease perforation or fistula formation will improve the overall response to therapy.

In summary, treatment of benign esophageal strictures is effective in the majority of patients, but not without risk that increases with adjunctive therapies for those patients with recurrent strictures or those refractory to dilation. Although placement of endoprostheses for benign esophageal strictures can be an effective adjunctive therapy, it is not without significant associated adverse events, and long-term clinical response is questionable. Based on current data, placement of an endoprosthesis should be considered as a last resort for patients with benign refractory strictures who have failed all other therapeutic options. Finally, for those who have strictures that transiently respond to therapy, daily self-dilation may be considered. For all the remaining, surgical referral can be considered.

### Self-Dilation

In a select group of patients with stenosis with transient response to dilation requiring frequent dilations to maintain luminal patency, daily esophageal self-dilation with a bougie dilator can be learned. Although this technique requires active patient participation, it can increase a patient's quality of life by decreasing dependence on frequent procedures. We reserve this technique

for patients who require frequent dilation to maintain patency over a prolonged period. We typically ensure that the patient is dilated to 15 mm and teach self-bougienage with a 13-mm dilator. This technique is effectively demonstrated on an ASGE video entitled *Esophageal self-dilation: a teaching guide for physicians (DV049)*.

### Esophageal Luminal Reconstitution

Surgical procedures and radiation to the esophagus may result in complete loss of the esophageal lumen, making standard dilation techniques ineffective due to the inability to pass even guidewires. Techniques for luminal reconstitution of completely obstructing complex radiation induced esophageal strictures have been described by a number of groups.<sup>52–55</sup> We confirm that there is total stenosis as tight complex strictures can usually be endoscopically remediated via a gastrostomy if wire passage via the oropharynx is unsuccessful. We use a combined retrograde endoscopic and anterograde laryngoscopic approach. The combined technique involves the passage of an endoscope through a gastrostomy tube site retrograde up the esophagus to the level of the obstruction. Using wires, catheters, scissors, and endoscopic dissectors, a track is made in the cephalad direction to the oropharynx. Visible transillumination, and at times fluoroscopy, are used to guide passage of a guidewire. Once the guidewire is passed proximally through the stricture, it is then used for anterograde passage of wire guided bougie and balloon dilators (Fig. 21.12). The esophagus is typically dilated to 15 mm and an NG tube bridled in place to maintain patency. Repeated dilation is then performed over the ensuing days and weeks to maintain the newly established tract and to allow it to epithelialize.<sup>52</sup>

**FIG 21.12** **A**, Retrograde approach using a pediatric endoscope introduced through a dilated PEG tube site and up the esophagus to the stricture. **B**, A wire was advanced through the stricture and out the mouth, followed by the retrograde passage of a wire guided bougie dilator.

## SUMMARY

Most esophageal strictures can be effectively and safely managed with esophageal dilation techniques. For strictures that recur at short intervals, repeat dilation with adjunctive therapies such as intralesional steroid injection and incisional therapy can be effective. If these techniques fail to maintain patency, then endoprosthetic placement may be considered, but a refractory stricture is not likely to respond well to intermittent placement and may require nearly continuous indwelling endoprosthetic treatment. It is important to remember the goal of therapy is to improve the patient's quality of life. As patients' risk tolerances differ, the escalation and order of therapy should be individualized.

## INTRODUCTION

Gastrointestinal foreign bodies (GIFBs) and food impactions are a common problem encountered by endoscopists, and, next to gastrointestinal bleeding, are the second most common endoscopic emergency encountered. Previous studies have suggested that between 1500 and 2750 deaths occurred in the United States secondary to GIFBs.<sup>1–2</sup> More recently, mortality from GIFBs has been shown to be significantly lower, with no GIFB reported deaths reported in over 850 adults and only one death in approximately 2200 children.<sup>4–10</sup> However, regardless of imprecise morbidity and mortality rates, serious complications and deaths occur as a consequence of foreign body ingestions.<sup>11–12</sup> Thus, because of their frequent occurrence and potential for negative consequences, it is important to understand which patients are in need of treatment, which techniques best treat GIFBs, and how to manage related complications.

Flexible endoscopy has become the treatment of choice for GIFBs and food impactions because it is safe and highly efficacious. Knowledge of the indications for endoscopic treatment, patient preparation, and accessory selection to achieve treatment success is crucial in the management of GIFBs. In addition, the specific techniques to safely and successfully treat food impactions, true ingested foreign bodies, and colorectal foreign bodies will be covered in detail in this review.

## NONENDOSCOPIC THERAPIES

A number of medical therapies have been considered as treatment of esophageal foreign bodies and food impactions. The smooth muscle relaxant glucagon is the most widely used and studied drug for the treatment of esophageal foreign bodies. Glucagon, given in doses of 0.5 to 2.0 mg, can produce relaxation of esophageal smooth muscle and lower esophageal sphincter by as much as 60%, with the potential to permit passage of the impacted food or foreign body.<sup>14–15</sup> Success with primary glucagon therapy ranges from 12% to 58% in treating food impactions.<sup>16–18</sup>

However, a small randomized study showed no benefit with the administration of glucagon over placebo.<sup>19</sup> Glucagon used in conjunction with endoscopy has shown that glucagon given at the time of endoscopy promotes clearance of the food bolus.<sup>20</sup> Glucagon may cause nausea, vomiting, and abdominal distention. Glucagon has little effect when a fixed obstruction is present, preventing passage of the foreign body. In a retrospective study, glucagon was ineffective in treating food impactions in patients with eosinophilic esophagitis.<sup>21</sup> Nifedipine and nitroglycerin are not recommended because of side effects and lack of efficacy.

The use of effervescent agents such as carbonated beverages have been described for treating esophageal impactions. These agents are purported to release carbon dioxide gas to distend the lumen and act as a piston to push the object from the esophagus into the stomach.<sup>22</sup> However, the effectiveness of this method is doubtful with perforations and aspirations having been reported associated with the use of gas-forming objects.<sup>23</sup> Similarly, the meat tenderizer papain is not recommended for the treatment of esophageal meat impactions because of risk of complications, including perforation and mediastinitis.<sup>24,25</sup>

Radiologic methods have been described for the treatment of esophageal foreign bodies. Under fluoroscopic guidance, Foley catheters, suction catheters, wire baskets, and magnets have been used to retract objects.<sup>26</sup> The most commonly described device is the Foley catheter; the balloon tip of the catheter is passed distal to the object, inflated, and then the object is withdrawn into the oropharynx. Success of Foley catheter extraction of esophageal foreign bodies under fluoroscopy has been described as more than 90%. However, all radiographic methods suffer from lack of control of the object, particularly at the level of the upper esophageal sphincter and hypopharynx. Complications may include nosebleeds, laryngospasm, aspiration, perforation, and even death.<sup>27</sup> Data on radiologic methods for foreign body removal is primarily limited to the esophagus. Radiographic methods are generally recommended only if flexible endoscopy is not available.

**Abstract**

Gastrointestinal foreign bodies are comprised of food bolus impactions and both intentionally and unintentionally ingested and inserted true foreign objects. This review covers diagnostic and therapeutic use of non-endoscopic and endoscopic methods in managing gastrointestinal foreign bodies. With flexible endoscopy being the primary treatment modality of gastrointestinal foreign bodies detailed attention is centered on the endoscopic success, techniques, equipment, and complications used for the management of food impactions and the varying types of true foreign bodies.

food impaction

## ENDOSCOPIC METHODS

Multiple large series have reported the success rate for endoscopic treatment of GIFFBs to be more than 95%, with complication rates of less than 5%.<sup>42–43</sup> Timing and indication for the treatment of GIFFBs should always be planned with the knowledge that 80% to 90% will spontaneously pass through the GI tract without complication.<sup>47</sup> Although conservative management may be effective in many cases of GIFFB, it is most appropriate to perform selective endoscopy for treatment based on the location, size, and type of foreign body ingested.<sup>38,54</sup>

Generally, all foreign bodies, including food impactions lodged in the esophagus, require urgent intervention. The risk for an adverse outcome from an esophageal foreign body or food impaction is directly related to how long the object or food dwells in the esophagus.<sup>55</sup> Ideally, no object should be left in the esophagus longer than 24 hours, and preferably the endoscopy should be performed within 12 hours of presentation. In particular, if the patient is in severe distress and unable to handle secretions, the risk for aspiration increases, and endoscopy should be done in the first 6 to 12 hours within presentation. It is not unusual, especially in children and in impaired adults, that there is a significant delay from ingestion to presentation.

Once in the stomach, most ingested objects will pass spontaneously and the risk of complications is much lower, thus making observation acceptable and endoscopic intervention may not be necessary. There are notable exceptions that will almost always require endoscopic intervention due to their increased likelihood of causing a complication or, with some objects, the likelihood that they will not pass from the stomach. Sharp and pointed objects are associated with perforation rates as high as 15% to 35%.<sup>56</sup> Sharp objects should be removed in an urgent fashion due to the risk of complication; removal may not be possible once the object is past the ligament of Treitz. Objects longer than 5 cm and round objects wider than 2 cm may not pass spontaneously and should be removed from the stomach with an endoscope at presentation or if they have not progressed in three to five days.

With the increasing use of device-assisted enteroscopy, case reports have detailed the use of these scopes to retrieve foreign bodies from the small bowel safely and effectively.<sup>36,37</sup> Balloon enteroscopy has been frequently used for removal of entrapped video endoscopy capsules, as well as migrated esophageal and enteric metal stents.<sup>38,39</sup> Furthermore, balloon enteroscopy has been shown to be safe and effective in objects that have been present in the small bowel a number of weeks after the objects were observed and given an opportunity to pass spontaneously.<sup>40</sup> Accessories including baskets, hoods, and forceps have been designed for the balloon enteroscopes to enable foreign body retrieval.

The type of sedation selected to facilitate endoscopy for the management of food impactions and ingested foreign objects should be individualized. Moderate sedation is adequate for the treatment of the majority of food impactions and simple foreign bodies in the adult population. Monitored anesthesia care or general anesthesia assistance may be required for uncooperative patients or patients who have swallowed multiple complex objects. This is due to the prolonged time associated with some cases, the necessity to protect the airway, and the need for repetitive esophageal intubation. The possibility of anesthesia assistance should be available even for cases that are initiated with moderate sedation due to potential failure to not complete the case or

respiratory complications in these cases. Endoscopy for treatment of foreign bodies in the pediatric population is usually performed with the aid of anesthesia and endotracheal intubation.<sup>41</sup>

For management of impactions and ingestions below the level of the laryngopharynx (esophagus, stomach, small intestine), flexible endoscopy is almost always preferred.<sup>42</sup> Rigid esophagoscopy and flexible nasoendoscopes can be used for esophageal foreign bodies, but provide no additional benefit and are often available to only a few endoscopists.<sup>43,44</sup> A comparison of rigid versus flexible endoscopes in the treatment of esophageal foreign bodies found significantly less perforations with flexible endoscopes.<sup>42</sup> Use of rigid endoscopes and laryngoscopes is usually performed by otolaryngologists. Rigid esophagoscopy will almost always require general anesthesia with endotracheal intubation. Laryngoscopes with the aid of a Kelly or McGill forceps can be useful for proximal foreign bodies and small sharp objects in the hypopharynx. An anesthesia video laryngoscope can be used for objects at the hypopharynx and upper esophageal sphincter when gastroenterology and otolaryngology flexible scopes have failed to identify and remove the object.<sup>44</sup>

Availability of and familiarity with multiple endoscopic retrieval devices for the removal of foreign bodies and food impactions is critical (Table 22.1). An endoscopy suite and/or travel cart should be equipped with at least the following to allow successful treatment of a variety of GIFFBs: a rat tooth or alligator grasping forceps, polypectomy snare, Dormia basket, and retrieval net<sup>45</sup> (Fig. 22.1). Use of a double channel therapeutic endoscope can allow passage of two retrieval devices simultaneously if needed. Removal of foreign bodies with standard forceps is rarely successful and not recommended. A transparent vacuum cap similar to that used for esophageal banding or endoscopic mucosal resection may be used in challenging food impactions. Overtubes of 45 and 60 cm in length should be available to the endoscopist (Fig. 22.2). An overtube allows protection of the airway, multiple exchanges of the endoscope, and mucosal protection from sharp objects.<sup>46</sup> The longer 60-cm overtube is designed to be advanced into the stomach, thereby enabling the retrieval of sharp and complex objects from the stomach without injuring the lower esophageal sphincter. Due to the size of overtubes and potential trauma upon insertion, their use is limited in the pediatric population and patients with suspected eosinophilic esophagitis. An alternative adjunct for extraction of sharp objects is a latex protection hood, which fits onto the tip of the endoscope<sup>47,48</sup> (Fig. 22.3).

When planning for extraction of complex objects, it may be valuable to go through an ex vivo dry run on a similar object

**TABLE 22.1 Equipment for Treatment and Removal of Gastrointestinal Foreign Bodies and Food Impactions**

Endoscopes	Overtubes	Accessory Equipment
Flexible endoscope	Standard esophageal overtube	Retrieval net
Rigid endoscope	45- to 60-cm foreign body overtube	Grasping forceps
Laryngoscope		Dormia basket
		Polypectomy snare
		Transparent vacuum cap
		Inflatable balloons
		Latex protector hood
		Kelly or McGill forceps

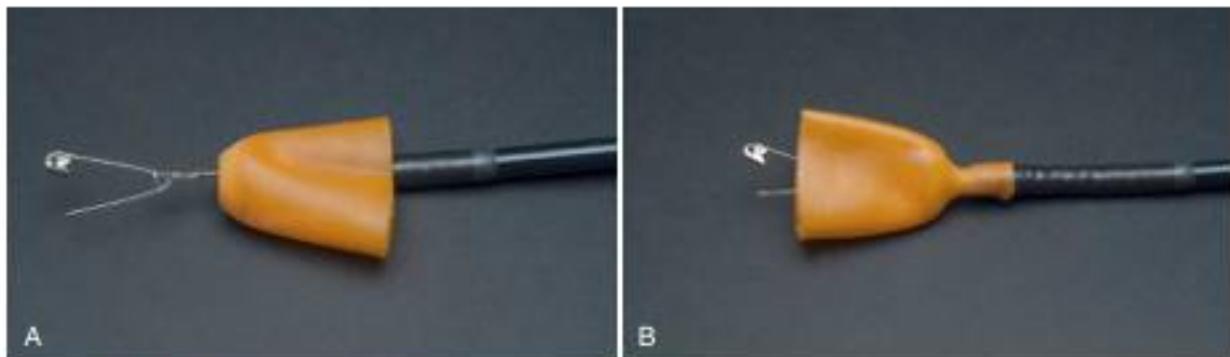

when considering retrieval devices and extraction technique.<sup>4</sup> Success and speed of retrieval of the foreign body have been shown to be directly related to endoscopist experience.<sup>15</sup> When personnel or facilities are not available to accomplish success endoscopically, consideration should be given to transferring the patient to another more experienced center.

**FIG 22.1** Endoscopic accessory and retrieval devices necessary for treatment of food impactions and foreign bodies. (Left to right: Basket, retrieval net, snare, rat-tooth forceps).

**FIG 22.2** Esophageal (45 cm) and gastric (60 cm) overtubes.

**FIG 22.3** **A**, Use of a protector hood wherein the hood is flipped back allowing visualization and grasping of a sharp object. **B**, When the protector hood is pulled through the lower esophageal sphincter, it flips forward covering the sharp object and protecting the mucosa.

Prior to endoscopic therapy, assessment of the patient's airway, ventilatory status, and risk for aspiration are crucial. A neck and chest examination looking for crepitus, erythema, and swelling can suggest a proximal perforation. Lung examination should be performed to detect the presence of aspiration or wheezing. An abdominal examination should be performed to evaluate for signs of perforation or obstruction. If physical exam evidence of aspiration or perforation is present, chest and/or abdominal radiographs should be performed.

## SPECIFIC FOREIGN BODIES

### Food Impaction

Given that food boluses may pass spontaneously, the need for endoscopic intervention is often based on the persistence of symptoms. Patients with clinical signs of complete or near-complete esophageal obstruction who are unable to swallow their own oropharyngeal secretions should undergo urgent upper endoscopy. The endoscopic intervention should be completed at least within 24 hours of symptom onset and ideally within the first 6 to 12 hours. Performing an endoscopy in the first 6 to 12 hours after symptom onset may allow for endoscopic removal of the food bolus in one piece before it has a chance to soften and break down, making extraction more challenging and time consuming.<sup>30</sup> An increased risk for complications is proportional to the duration of esophageal food impaction.<sup>31-35</sup> Patients who have procedures completed after 24 hours of symptoms onset are more likely to develop esophageal ulcerations and prolonged odynophagia.<sup>34</sup> Furthermore, patients with esophageal impactions for more than 24 hours have more than a 14-fold risk of developing a major complication, such as perforation.<sup>35</sup>

The primary method to endoscopically treat food impaction is the push method, with success rates well over 90% and minimal complication rates.<sup>36</sup> Before the food impaction is pushed into the stomach, an attempt to maneuver the endoscope around the food into the stomach should be made. Generally, if the endoscope can be advanced around the food impaction into the stomach, the food impaction can be then safely pushed with gentle pressure using the tip of the endoscope into the stomach without difficulty. This technique allows assessment of any obstructive esophageal pathology distal to the impacted food. If the endoscope cannot maneuver around the food impaction, gentle pushing pressure can be safely attempted. However, if significant resistance is

encountered, the pushing should not continue as this can lead to a tear and perforation. Particularly in patients with a hiatal hernia, the gastroesophageal junction may have a left turn, thus pushing the food bolus from the right side may allow easier and safer passage of the obstructing bolus into the stomach. Larger boluses of impacted meat can be broken apart with the endoscope or an accessory prior to pushing the smaller pieces into the stomach safely. When the endoscope cannot first pass the food bolus, a method has been described wherein a Savary wire is passed into the stomach and the food is subsequently pushed into the stomach through the use of Savary-Gillard dilators (Cook Medical, Bloomington, IN).<sup>37</sup> This method has been shown to be successful but should be used with caution because of the lack of visualization.

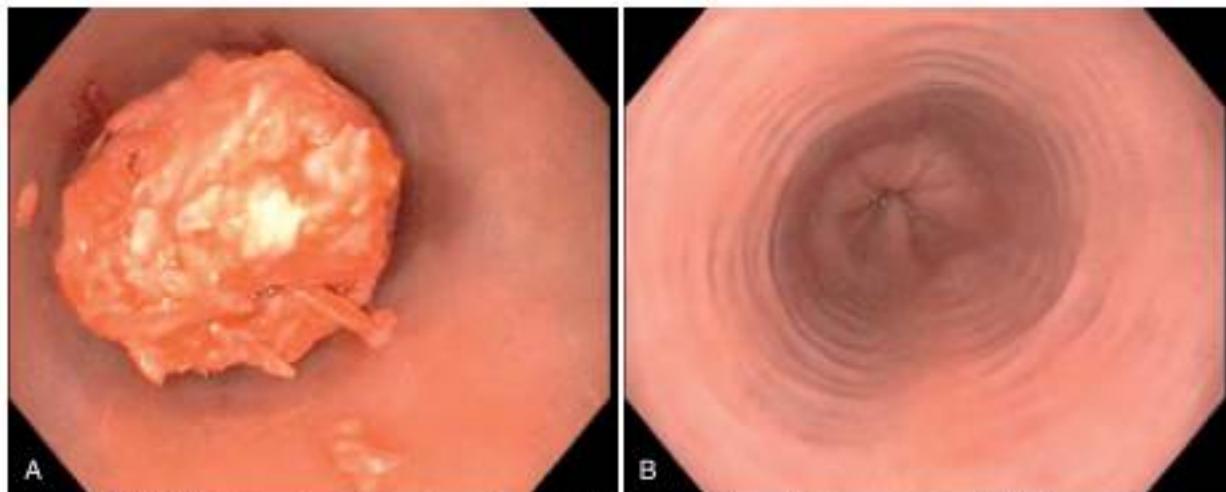

Eosinophilic esophagitis has increasingly been associated with esophageal food impactions and is thought to be the leading cause for patients presenting to emergency departments with impacted food boluses.<sup>38,39</sup> Reports indicate that food impaction in patients with eosinophilic esophagitis can be treated effectively and safely with the push method.<sup>40</sup> However, care should be taken to minimize inducing mucosal tears.<sup>41</sup> Particular care should be taken when using rigid endoscopes if eosinophilic esophagitis is suspected as perforation rates with rigid scopes in this patient population has been reported as high as 20%.<sup>42</sup> If eosinophilic esophagitis is suspected, mucosal biopsies can be obtained after removal of the food bolus (Fig. 22.4). Many patients with eosinophilic esophagitis do not have esophageal biopsies obtained after food bolus removal leading to a delay in treatment and possible underestimation of disease prevalence.<sup>43</sup>

Food impactions that cannot be pushed into the stomach must be dislodged and removed proximally. Proximal removal can be achieved with various endoscopic retrieval devices, including snares, baskets, nets, and alligator, shark, rat-tooth or tripod forceps. When grasping the food bolus with a snare, basket, or forceps, the food should be pulled tight against the endoscope and then the device, scope, and food impaction should be withdrawn simultaneously to limit the risk of releasing the food at the proximal esophageal sphincter or posterior oropharynx.

Use of a net may reduce the risk of a food bolus dislodging in the hypopharynx. In addition, using a retrieval net has been shown to result in fewer passes and shorten overall procedure duration.<sup>44</sup> A dedicated food bolus retrieval net can be useful for removing large pieces of food without the use of an overtube because the food can be satisfactorily secured within the net, thus reducing the risk of aspiration of the ingestate.<sup>45</sup> For food impactions that are difficult to dislodge, a novel technique using a through-the-scope balloon passed distal to the impacted food then inflated and withdrawn proximally has been reported.<sup>46</sup> For lengthy or complex esophageal food impactions, an esophageal overtube should be used as it protects the airway and allows multiple exchanges of the endoscope during retrieval.

Transparent plastic hoods or caps, such as those used to perform variceal band ligation and endoscopic mucosal resection, have been used successfully for the removal of large, tightly impacted meat boluses. With the cap secured to the tip of the endoscope, the device can be used to suction the food into the cap and to withdraw the bolus retrograde with constant suction applied.<sup>46,47</sup> Use of a Dormia basket within a transparent cap has also been used in the extraction of food impactions.<sup>48</sup> Two large Asian studies demonstrated that sharp food impactions, usually fish or chicken bones, are best retrieved with a rat-tooth forceps.<sup>49,50</sup> Ideally, the sharp food should be grasped at one end with the most sharp end trailing as the item is removed to limit the risk of tear or perforation.

More than 75% of patients with food impactions have associated esophageal pathology with strictures being the most common finding.<sup>4,51,52</sup> In addition, approximately half of patients with food bolus impactions have abnormal 24-hour pH studies and/or esophageal manometry. If an esophageal stricture or Schatzki's ring is present after the food bolus is cleared, it can be safely and effectively dilated after the food impaction is removed if circumstances allow. More often, mucosal abrasions, erosions, or erythema exist due to the impacted food for an extended period and the dilation is delayed for 2 to 4 weeks, during which patients should be prescribed proton pump inhibitor therapy. When endoscopic findings such as longitudinal furrows, multiple

**FIG 22.4** **A**, Esophageal food impaction with large piece of meat that was treated with the push method. **B**, More proximal esophagus in the same patient demonstrating rings. Esophageal mucosa biopsied at same time of treatment of food impaction with biopsies consistent with eosinophilic esophagitis.

rings, and white exudates are present, biopsies should be obtained from throughout the esophagus to evaluate for eosinophilic esophagitis.<sup>71</sup> Lack of appropriate follow-up for patients, particularly those with strictures or rings, has been shown to be a predictor for recurrent food impactions.<sup>74</sup>

### True Foreign Bodies

True foreign bodies (nonfood ingestions) can occur from either intentional or unintentional ingestion. Children between the ages of 6 months and 6 years are the most common cohort to intentionally ingest true foreign bodies.<sup>4,75</sup> In adults, true foreign body ingestion is more common in patients who are acutely intoxicated with alcohol, have a psychiatric disorder, developmental delay, seek secondary gain, or are edentulous.<sup>4,76,77</sup> Once ingested, a higher rate of recurrent ingestion is found in males, prisoners, and patients with a psychiatric disorder.<sup>77</sup>

### Sharp and Pointed Objects

The ingestion of sharp and pointed objects carries a significant risk of complications, including perforation. Perforation can occur in up to 15% to 35% of patients and accounts for one-third of all perforations from GIFBs.<sup>78</sup>

Sharp and pointed objects retained in the esophagus are thus considered a medical emergency and should be removed within 6 to 12 hours.<sup>79</sup> Objects at the cricoopharyngeus may be best visualized and removed with a laryngoscope. Due to risk of complications, any sharp and pointed object within reach of the endoscope should be removed urgently if this can be done safely. Prior to the removal of sharp objects, Chevalier Jackson's axiom should be remembered: "advancing points puncture, trailing points do not."<sup>80</sup> To accomplish this, the foreign body should be grasped and oriented so that the sharp end trails on withdrawal to reduce the risk of perforation and mucosal laceration upon removal.<sup>81</sup> This sometimes entails pushing the object into the stomach with the endoscope and then orientating the sharp edge to be the trailing point upon withdrawal. For sharp and pointed objects, retrieval is best achieved with grasping forceps such as rat tooth, shark tooth, or alligator forceps, tripod forceps, a polypectomy snare, or biliary stone retrieval basket.<sup>82</sup> Retrieval nets tend to shear in the removal of sharp objects and may compromise visualization.

In some circumstances, use of an overtube should be considered to protect the esophagus and oropharynx from the sharp object. Long, pointed objects in the esophagus and stomach can be grasped and withdrawn into the overtube; the entire assembly, including the sharp object, the endoscope, and the overtube can then be removed in unison. An alternative device to an overtube, for the extraction of sharp objects, is a retractable latex hood attached to the tip of the endoscope. The flexible latex trails the endoscope tip. Thus, as the endoscope is being advanced the hood is pointed proximally. When the endoscope is pulled back through the lower esophageal sphincter, the hood flips over the grasped object and protects the mucosa during withdrawal<sup>83,84</sup> (see Fig. 22.3).

Although associated with an increased risk of perforation, most sharp or pointed objects beyond reach of the endoscope will pass unimpeded and be eliminated through the GI tract without complication. Because of the increased risk of perforation, sharp and pointed objects should be followed by serial daily radiographs to ensure progression (Fig. 22.5). If a sharp or pointed object fails to progress over three days, or if there is evidence of a complication such as abdominal pain, fever, nausea, bleeding,

**FIG 22.5** Radiograph of large, ingested knife located within the stomach.

or overt signs of perforation, surgical intervention should be considered. Balloon assisted enteroscopy is a viable option when a sharp object has passed the duodenum.<sup>80,82</sup>

### Long Objects

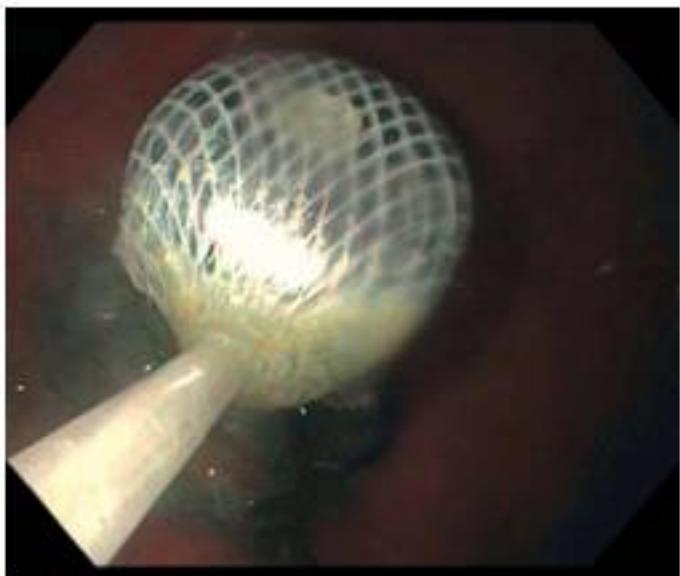

Ingested objects longer than 5 cm (2 inches), and especially those longer than 10 cm (4 inches), such as toothbrushes, forks, and spoons, have difficulty passing through the pylorus and duodenal sweep. This can lead to an obstruction or perforation at these locations. Removal is best attempted while the object remains in the stomach, as duodenal removal is more difficult given the smaller diameter and tortuous lumen. The most commonly ingested long objects are pens, pencils, toothbrushes, and eating utensils. Removal of these objects is sometimes challenging and caution to avoid mucosal injury or perforation should be taken. Grasping forceps and polypectomy snares are commonly used to secure and remove long objects. Long objects should be grasped at one end and oriented longitudinally to permit removal (Fig. 22.6). Grasping a long object near the middle will not allow it to be withdrawn safely through the upper gastrointestinal tract sphincters. For extraction of long sharp objects, a 60 cm overtube can be used, which will cross the lower esophageal sphincter when introduced. The object can be grasped with the endoscope and a retrieval device and then brought into the overtube to make it align in a vertical position without causing mucosal injury.

### Blunt Objects: Coins, Batteries, and Magnets

Small blunt objects, such as pieces of toys, disc or button batteries, and coins, are the most commonly ingested objects by children younger than 4 years old.<sup>85</sup> Blunt objects in the esophagus should be removed promptly with the use of grasping forceps, snare, retrieval basket, or net. Coins impacted in the esophagus can result in pressure necrosis of the esophageal wall and lead to perforation or fistulization. A coin of any size can become lodged

**FIG 22.6** Removal of pencil with snare. The pencil is grasped on the very end with the sharp point trailing.

**FIG 22.7** Retrieval net used in the removal of a blunt object (lip gloss) that was pushed from the esophagus into the stomach and then removed without difficulty.

in the esophagus of children, but ingested coins, in particular dimes and pennies measuring 17 and 18 mm, will usually pass through the adult esophagus. Coins located in the distal esophagus on imaging are twice as likely to pass spontaneously than coins in the proximal esophagus.<sup>51</sup>

Retrieval nets are the preferred retrieval device as they allow capture and secure removal of coins and most small blunt objects (Fig. 22.7).<sup>44</sup> This allows for additional airway protection as the object is pulled past the oropharynx. Grasping forceps and biliary stone retrieval baskets are also effective but the objects are often slightly less secure. Standard biopsy forceps and snares are not recommended because they fail to secure coins reliably during extraction and can lead to airway compromise. If it is difficult to capture a blunt object in the esophagus, it is generally safe to gently push the object into the stomach, where there is more room to negotiate. If there is concern of airway compromise, particularly for removal of coins in the esophagus, endotracheal

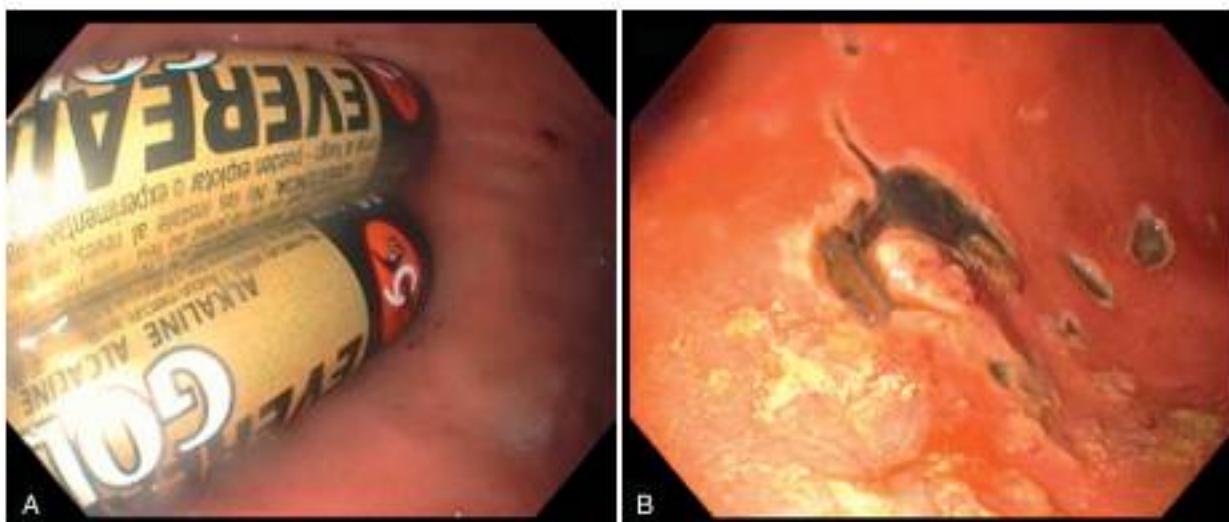

intubation should be considered. An overtube can also be used for airway protection.

Once a small blunt object enters the stomach, conservative outpatient management is appropriate for many patients.<sup>51</sup> Exceptions to this include patients with surgically altered digestive tract anatomy, those with symptoms, and those who have ingested large blunt objects. In adults, the pylorus will allow passage of most blunt objects up to 25 mm in diameter, which includes all coins except half-dollars (30 mm) and silver dollars (38 mm). Otherwise, once in the stomach, a regular diet is appropriate, with radiographic monitoring every 1 to 2 weeks to confirm progression or elimination. If after 3 to 4 weeks a blunt object has not passed, endoscopic removal should be performed.<sup>51</sup>

The incidence of small disc battery ingestion is increasing due to the increased use of lithium button batteries in electronics.<sup>52</sup> Disc batteries are of special concern because they may contain an alkaline solution that can rapidly cause a liquefaction necrosis of esophageal tissue resulting in perforation or fistula formation. The disc batteries can also lead to additional mucosal damage due to the local electrical current. Disc batteries are present in many small toys, watches, calculators, and other electronic devices that are accessible to young children. Disc battery ingestion occurs most commonly in younger children, with approximately 10% becoming symptomatic.<sup>53</sup> Therefore any clinical suspicion of a disc battery in the esophagus should prompt emergent endoscopy. Grasping forceps and snares are generally ineffective for disc battery removal, but use of a retrieval net permits successful removal in almost 100% of cases.<sup>54</sup> Protection of the airway with an overtube or, in pediatric patients, endotracheal intubation, is crucial in retrieval of disc batteries. Once in the stomach or small intestine, disc batteries rarely cause clinical problems and can be observed radiographically. Once in the duodenum, 85% will pass through the GI tract within 72 hours.<sup>55</sup> Batteries located beyond the esophagus require endoscopy if the patient develops symptoms or the battery remains in the stomach for 48 hours on repeat radiograph.<sup>56</sup>

Cylindrical batteries appear to cause symptoms less frequently with no reports of major life-threatening injuries and only approximately 20% having some minor symptoms after ingestion.<sup>57</sup> Due to their size, cylindrical batteries do not have the same risks of electrical discharge compared to disc batteries. Cylindrical batteries should be removed from the esophagus within 24 hours if possible. If in the stomach, batteries larger than 20 mm or those that have not progressed in 48 hours should be removed endoscopically (Fig. 22.8).

Small coupling magnets have become popular as children's toys. Ingested magnets within the reach of the endoscope should also be removed on an urgent basis. Although a single magnet will rarely be a cause of symptoms, concern exists if multiple magnets are ingested or if magnets were ingested with other metal objects. This can result in magnetic attraction between the objects and coupling between interposed loops of bowel with subsequent pressure necrosis, fistula formation, and bowel perforation.<sup>51,52</sup> Removal should be performed urgently when the magnets are more likely to be within reach of a standard endoscope; this can be achieved with grasping forceps, retrieval net, or basket. Magnetic attraction to metallic retrieval devices may ease the task of removal.<sup>51,54</sup> If multiple magnets have been ingested, a postprocedure x-ray can be performed to ensure that all have been retrieved. If more than one magnet is not within endoscopic reach, surgical removal versus enteroscopy should be performed.

**FIG 22.8** **A**, Cylindrical batteries in stomach that did not pass after 48 hours of observation. Removed with snare with endotracheal intubation. **B**, Stomach ulceration caused by cylindrical batteries.

### Narcotic Packets

Narcotic packets are often filled with cocaine, amphetamines, or heroin and endoscopic removal is contraindicated because of the high risk of package perforation with resultant drug overdose, which can be fatal.<sup>51</sup> Observation on a clear liquid diet is recommended with serial radiographs. Operative intervention is indicated when bowel obstruction, failure to progress, or drug leakage/toxicity is suspected. A large study indicated that up to 45% may require surgery with gastrostomy, enterotomy, or colotomy performed based on the location of the packages.<sup>55</sup>

### Colorectal Foreign Bodies

Ingested objects uncommonly become lodged in the colorectum. More commonly, colorectal foreign bodies are inserted into the rectum intentionally or unintentionally. Males are much more likely than females to present with a rectal foreign body, with a ratio of 37:1.<sup>56</sup> The initial assessment should include an evaluation for signs of peritonitis and need for a laparotomy. Radiographs should be obtained prior to attempting removal of colorectal foreign bodies for better visualization of the location, orientation, and configuration of the object. To avoid health care provider injury, attempts at manual removal or digital rectal examination should be deferred until the presence of a sharp or pointed object has been excluded.

Most objects (76%) can be removed nonsurgically.<sup>57</sup> Manual digital extraction may be successful for the removal of small, blunt objects in the distal rectum that are palpable on rectal examination.

Nonpalpable and sharp or pointed objects should be removed under direct visualization with the use of a rigid proctoscope or flexible sigmoidoscope.<sup>57</sup> Standard retrieval devices can be used as described earlier for the upper digestive tract. The use of obstetric tools has also been reported.<sup>58</sup> A latex hood or overtube can be particularly useful in removing long, sharp, pointed objects to protect the rectal mucosa from laceration and to overcome the tendency of the anal sphincter to contract on attempted removal of objects. Although conscious sedation will

often facilitate removal, general anesthesia can allow maximum dilation of the anal sphincter to help remove larger and more complex objects.<sup>59</sup>

Operative intervention is indicated for any suspected complications secondary to a rectal or colon foreign body, including perforation, abscess, and obstruction, and for failure of endoscopic removal. Patients with objects retained within the sigmoid colon are more than twofold more likely to require an operative intervention compared to those with objects within the rectum.<sup>50</sup> Furthermore, complications are more common when the object is proximal to the rectum.<sup>60</sup>

### PROCEDURE-RELATED COMPLICATIONS

Although the reported complication rate associated with endoscopic removal of gastrointestinal foreign bodies and food impactions is low (0% to 1.8%), it is thought to be much higher in practice (more than 5%).<sup>40,50,51,56,101</sup> Perforation is the most feared complication, although aspiration and sedation-related cardiopulmonary complications may also occur. Factors that increase the risk for complications include removal of sharp and pointed objects, an uncooperative patient, multiple and/or deliberate ingestions, and extended duration of time from food impaction or foreign body ingestion to endoscopy.<sup>11</sup>

Limitations to Endoscopic Assessment of EoE, 263	Endoscopic Findings as Therapeutic Endpoints, 265	Conclusion, 266
Importance of Standardized Nomenclature and Definitions, 263		

## INTRODUCTION

Eosinophilic esophagitis (EoE) is a chronic, immune-mediated clinicopathological disease characterized by esophageal symptoms, eosinophilic inflammation localized to the esophagus, and the absence of other causes of eosinophilia.<sup>1,2</sup> This evolving definition, devised after multiple iterations by a consensus panel, excludes endoscopic findings as part of the diagnostic criteria. Nonetheless, such findings are often the first clue to the gastroenterologist that a patient may have EoE. Moreover, endoscopic features provide important clinical information regarding the underlying phenotype of the disease, which can have both prognostic and therapeutic implications. A comprehensive assessment of endoscopic features, alongside clinical and histopathological data, can therefore provide a more comprehensive assessment of the patient's overall disease activity and severity, thereby informing management decisions.

## LIMITATIONS TO ENDOSCOPIC ASSESSMENT OF EOE

The relevance of endoscopic features in EoE has historically been challenged by concerns of inadequacies, including reports of limited sensitivity and interobserver agreement. Moreover, early retrospective studies reported a normal endoscopic appearance in approximately one-third of children with EoE.<sup>3</sup> Studies evaluating interobserver agreement among gastroenterologists who were shown still images demonstrated poor to fair agreement, which was independent of practice setting, patient volume, or use of narrow-band imaging, suggesting that perhaps we are not all "seeing the same things."<sup>3,4</sup> A meta-analysis reviewing 80 original articles and 20 abstracts found a pooled prevalence of 44% for rings, 21% for strictures, 9% for narrow-caliber esophagus, 48% for linear furrows, 27% for white plaques, and 41% for edema.<sup>5</sup> The diagnostic sensitivity for these features ranged from 15% to 48%. Interestingly, when only prospective studies were included, one or more endoscopic abnormalities were found

in 93% of patients. These findings highlight important inadequacies in reporting endoscopic features.

## IMPORTANCE OF STANDARDIZED NOMENCLATURE AND DEFINITIONS

The primary endoscopic features reported in EoE include longitudinal furrows (vertical lines), white exudates (plaques), rings (trachealization), strictures, edema (mucosal pallor or decreased vascularity), narrow-caliber esophagus, and "crêpe-paper" mucosa<sup>1,2,6,7</sup> (Table 23.1). Variable terminology has been used to describe these findings and this has led to inconsistency in reporting features attributable to EoE. Rings have been referred to as trachealization, corrugation, and felinization. Although some use these terms interchangeably, there are differences among these descriptors. Felinization traditionally refers to transient plications in the esophageal mucosa that occur during short-duration, axial shortening events such as retching, belching, or swallows. The "ripples" are often visualized by radiologists during barium swallows and completely efface spontaneously within seconds or with luminal distension with air. Such transient plications should not be confused with the fixed rings seen in EoE, which do not efface and are accentuated with air insufflation (Videos 23.1 and 23.2).<sup>8</sup> Appreciating this distinction between transient and fixed rings is important in establishing consistency among endoscopists. Multiple fixed rings of the esophagus have been confused with congenital esophageal stenosis. However, most cases of congenital esophageal stenosis do not produce a trachealization pattern, but instead a single fixed stenosis of the esophageal body.

Endoscopically characterized inflammatory features of EoE include edema, furrows, and exudates (Video 23.3). Edema is another term that has shown variability in reporting across endoscopists, in part because visualization of loss of vascular findings is highly dependent upon the contractile state of the esophagus and degree of luminal distension. Moreover, it may be neglected during routine reporting of esophagogastroduodenoscopy (EGD)

### Abstract

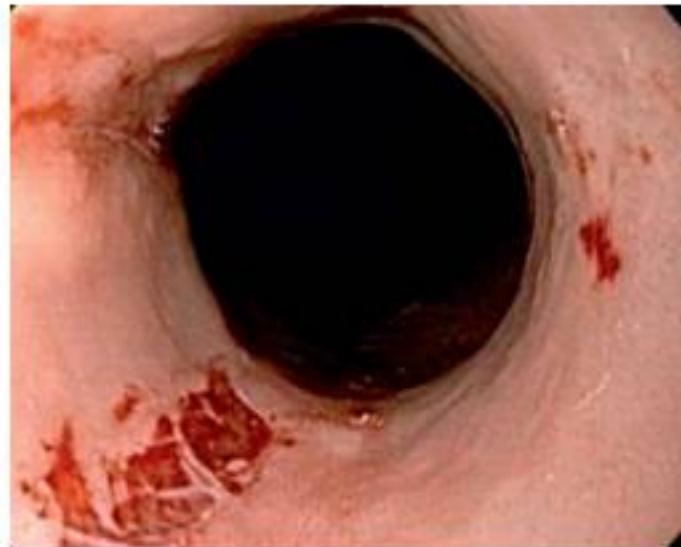

There have been significant advances in our understanding of the mechanisms that drive the inflammatory and remodeling consequences of eosinophilic esophagitis (EoE). We have learned that standardizing definitions has helped clinicians and researchers define adequate therapeutic goals, allowing for a common language to be spoken among physicians. Although not a part of the diagnostic criteria, endoscopic findings play a critical role in the global assessment of disease severity, and are often the first clue to a physician that a patient has EoE. Moreover, initial severity of endoscopic findings has important clinical implications with regard to treatment options, including the need for dilations and predicting the effectiveness of medical therapies. Finally, given the discord between patient-reported symptoms and histologic outcomes, endoscopic features may serve as a more reliable therapeutic marker. Therefore, a comprehensive assessment of a patient's symptoms, histology, and endoscopic findings is critical in ascertaining a global assessment of a patient's disease phenotype to determine an adequate treatment plan.

fibrostenosis

**TABLE 23.1 Primary Endoscopic Features Reported in Eosinophilic Esophagitis**

Endoscopic Feature	Comment
Edema	Mucosal pallor or decreased vascularity. Best assessed either in real-time or with video assessment as vascular markings are diminished during esophageal contractions.
Rings	Often confused with feline esophagus (transient plications). Best appreciated when esophagus is fully inflated.
Exudates	Often confused with <i>Candida</i> esophagitis infection. Often track along furrows.
Furrows	Longitudinal "track marks" or lines along the esophagus. Blood from biopsies can fill the indentations and aid in detection.
Strictures	Can be focal or diffuse. Distal strictures best appreciated on retroflexion. Precise determination of diameter is difficult.
Crêpe-paper esophagus	Fragile mucosa with disruption or sloughing from passage of an endoscope.
Narrow-caliber esophagus	Difficult to appreciate with endoscopy. Better defined by barium esophagram or functional luminal imaging probe.
"Tug" sign	Subjective resistance or "stiffness" appreciated when taking biopsies (suggests underlying fibrosis).

**FIG 23.1** Crepe paper esophagus (also referred to as mucosal fragility or laceration upon passage of an endoscope).

examinations. Lower resolution imaging on older generation endoscopes or transnasal endoscopes may impair detection of vascular markings. Exudates, which often track along longitudinal furrows, may be confused with white plaques from *Candida* esophagitis, and thus may be misdiagnosed. Crepe paper esophagus has been described as sloughing of esophageal mucosa during passage of an endoscope, perhaps secondary to subepithelial fibrosis or mucosal fragility (Fig. 23.1). A "tug" sign, described

as stiffness or resistance when taking esophageal biopsies, is inherently difficult to standardize due to its subjective nature.<sup>9</sup>

Endoscopic assessment of strictures of the esophagus in EoE is often challenging. Narrow-caliber esophagus is often difficult to consistently report on endoscopy given the absence of a standardized definition. The degree of radial narrowing and axial involvement that characterizes an esophageal stricture as narrow-caliber esophagus has not been specified. Recently, a luminal diameter of less than 17 to 20 mm involving more than 50% of the length of the esophagus has been proposed as diagnostic criteria.<sup>10</sup> Accurate assessment of luminal diameter is, however, imprecise, particularly in patients with proximal or diffuse involvement. A 2014 study evaluating the sensitivity and specificity of identifying narrow-caliber esophagus (in this case defined as < 21 mm in diameter) on EGD compared with barium esophagram revealed poor sensitivity (14.7%) and modest specificity (79.2%) of endoscopy.<sup>11</sup> The same limitation applies for measurement of discrete strictures, wherein stenoses between 12 and 20 mm may be overlooked due to lack of focality or superimposed constriction by the lower esophageal sphincter and crural diaphragm.

### EOE ENDOSCOPIC REFERENCE SCORE (EREFS)

Due to the variability and heterogeneity of endoscopic findings, a standardized classification and grading system was developed and subsequently validated to describe the endoscopic findings of EoE.<sup>12</sup> This system, referred to as the EoE Endoscopic Reference Scoring system, or EREFS, provides standardized nomenclature for five major features of EoE (edema, rings, exudates, furrows, and strictures) and includes a grading system to define severity of these individual findings (Fig. 23.2). In the original validation study, this grading system demonstrated good agreement for edema, rings, exudates, and furrows ( $\kappa = 0.40\text{--}0.54$ , 71%–81% pairwise agreements) and for strictures and crêpe-paper esophagus ( $\kappa = 0.52$  and  $0.58$ , 79% and 92% agreement). Despite good agreement, crêpe-paper esophagus was excluded from the final scoring system due to its low prevalence. Narrow-caliber esophagus was excluded due to lack of an operational definition.

Since its introduction, the EREFS grading system has been independently validated in a European study. Inter- and intraobserver agreement between four expert and four trainee endoscopists using an atlas of still images from 30 patients was assessed.<sup>13</sup> The authors found good interobserver agreement for rings ( $\kappa = 0.70$ ), exudates ( $\kappa = 0.63$ ), and crêpe-paper esophagus ( $\kappa = 0.62$ ), moderate for furrows ( $\kappa = 0.49$ ) and strictures ( $\kappa = 0.54$ ), and poor for edema ( $\kappa = 0.12$ ). Intraobserver agreement was substantial for rings, furrows, and crêpe-paper esophagus, moderate for exudates and strictures, and less than chance for edema. The low agreement for edema was likely affected by the use of still rather than video images. No difference was noted between expert and trainee endoscopists.

Compared to prior studies, where endoscopic identification of esophageal abnormalities was 83% to 93% as reported in a meta-analysis, prospective utilization of the EREFS system has identified abnormalities in over 95% of patients with EoE.<sup>12,13</sup> This suggests that this system may also have utility as a diagnostic tool given its high sensitivity. Moreover, the clinical relevance of endoscopic severity assessment has also recently been ascertained. The severity of EREFS subscores has been associated with patient-reported global symptom activity, and food impaction risk has been linked to ring severity.<sup>14,15</sup> A 2015

EoE Endoscopic Reference Score (EREFS)				
	Grade 0	Grade 1	Grade 2	Grade 3
<b>Edema</b> (loss of vascular markings)				
• Grade 0: Distinct vascularity				
• Grade 1: Absent or decreased				
<b>Rings</b> (trachealization)				
• Grade 0: None				
• Grade 1: Mild (ridges)				
• Grade 2: Moderate (distinct rings)				
• Grade 3: Severe (scope will not pass)				
<b>Exudate</b> (white plaques)				
• Grade 0: None				
• Grade 1: Mild (<= 10% surface area)				
• Grade 2: Severe (> 10% surface area)				
<b>Furrows</b> (vertical lines)				
• Grade 0: None				
• Grade 1: Mild				
• Grade 2: Severe (depth)				
<b>Stricture</b>				
• Grade 0: Absent				
• Grade 1: Present				

**FIG 23.2** EoE endoscopic reference score (EREFS). (Modified from Hirano I, Moy N, Heckman MG, et al: Endoscopic assessment of the oesophageal features of eosinophilic oesophagitis: validation of a novel classification and grading system. Gut 62[4]:489–495, 2013.)

study evaluating physicians' judgment of overall disease activity found that EoE activity assessment by gastroenterologists is largely based on endoscopic findings and symptoms, rather than histopathology.<sup>16</sup>

## ENDOSCOPIC FINDINGS AS THERAPEUTIC ENDPOINTS

Therapeutic trials in EoE currently utilize symptomatic and histopathological endpoints as the primary determinants of successful therapy.<sup>17</sup> Symptoms of dysphagia, however, may improve as a result of behavioral changes, such as avoidance of hard texture foods, excessive mastication, and prolonged meal times, and thus may not accurately reflect disease activity. This type of adaptive behavior may explain the placebo response in terms of dysphagia. Using a validated patient-reported outcome instrument (eosinophilic esophagitis symptom activity index, or EESAI), symptoms were shown to have modest accuracy as an indicator of disease activity as determined by endoscopy and histology.<sup>18</sup> Further evidencing this symptom-histology dissociation is the observation that dysphagia responds dramatically to esophageal dilation, without affecting disease histology.<sup>19</sup> For these reasons, symptomatic improvement, although certainly an important goal of treatment, is not a reliable marker of disease activity as a therapeutic endpoint. Histologic improvement is also limited as a therapeutic marker, as correlation with patient-reported symptoms and physician-reported disease activity has been shown to be poor.<sup>12,18</sup>

The utility of grading endoscopic findings to predict response to treatment may have value, particularly in identifying various phenotypes of disease. Patients who have a predominantly "fibro-

stenoic" pattern of injury with high-grade stenoses benefit from esophageal dilations, irrespective of disease activity as measured by eosinophilic inflammation.<sup>19</sup> These patients demonstrate the consequence of remodeling changes in EoE, wherein lamina propria fibrosis is believed to be a primary determinant. Those with an "inflammatory" phenotype, characterized by presence of exudates and furrows with predominant eosinophilic inflammation, typically respond well to topical corticosteroid therapy and may not require esophageal dilations.<sup>20,21</sup> Topical therapy, however, does not appear to affect underlying fibrostenotic disease activity. A 2016 retrospective study found that the presence of severe esophageal strictures was a negative predictor of histologic response to topical steroids.<sup>22</sup> However, topical therapy is likely playing some role in modulating remodeling changes, as demonstrated by a study wherein the thickness of the esophageal wall in patients undergoing treatment with nebulized budesonide was measured via endoscopic ultrasonography. In this randomized, controlled trial, the authors found that when compared to controls, EoE patients demonstrated significant thickening of the esophageal submucosa and muscularis propria, which improved, but did not normalize after treatment.<sup>23</sup>

The use of EREFS as a grading tool also has important clinical implications in determining responsiveness to treatment. A 2016 study demonstrated that EREFS had a high degree of accuracy not only for diagnosis of EoE, but also for responsiveness to treatment.<sup>19</sup> This prospective study evaluated 67 patients with EoE who were treated with either topical steroids or dietary elimination, and compared their endoscopic findings to 144 controls. Not surprisingly, EREFS scores (0–9) were greater in EoE patients versus controls (3.88 vs. 0.42,  $p > 0.001$ ), and the authors were able to define a threshold score of two or

greater to identify EoE patients with 88% sensitivity and 92% specificity. After treatment, the scores decreased significantly in EoE patients. Another recent study (2017) presented the first randomized, placebo-controlled trial of topical steroids that included endoscopic outcomes as defined by EREFS. In this study, oral budesonide suspension resulted in significant reduction in EREFS scores compared with placebo (where scores were unchanged), and improvement in all subscores with the exception of strictures.<sup>12</sup>

In discussing the advantages of using endoscopic features, one also has to consider their limitations. First, not all patients have every endoscopic feature, so using endoscopic grading systems to measure improvement is limited in patients that do not display all features. Secondly, the role of endoscopic features in predicting histologic remission may be limited. A 2016 study evaluated the predictive values of endoscopic features in assessing disease activity (peak eosinophil count) in a review of endoscopic still images and histopathology by a blinded endoscopist and pathologist.<sup>24</sup> The authors found that individual endoscopic findings did not correlate with peak eosinophil count, though a composite score of fibrotic signs, inflammatory signs, and total EREFS correlated weakly to moderately, without high positive or negative predictive values. Though technically a negative study, one can glean that a global clinical and endoscopic assessment, as determined by the composite scores, is likely more clinically relevant than the correlation of one endoscopic feature with peak eosinophil count. Furthermore, the use of still images may have been a limitation, and future studies using video images are needed to control for this limitation.

## ALTERNATIVES AND ADJUNCTS TO ENDOSCOPIC ASSESSMENT

Identifying adequate targets for treatment has become an important goal in therapeutic trials and clinical practice. The ability of medical and dietary therapies to improve endoscopically visible inflammatory and structural alterations correlates with improvements in patient-reported outcomes and histologic assessments. As in inflammatory bowel disease, endoscopic mucosal healing, along with histologic and clinical improvement, will likely become the new therapeutic target for trials and clinical practice. Incorporating a validated grading system for endoscopic features will be paramount in standardizing therapeutic trials going forward. The role of other tools to assess remodeling changes is also yet to be determined. Although initially promising, endoscopic ultrasonography has been abandoned as a tool to assess remodeling, but measurements of mural compliance via the functional luminal imaging probe (FLIP) has yielded promising results. By using a multichannel electrical impedance catheter and manometric sensor surrounded by an infinitely compliant bag, the mechanical properties of the esophagus can be measured. Initial studies showed a significant reduction in esophageal distensibility in EoE patients when compared with controls.<sup>25</sup> A subsequent study found that patients with a history of food impactions exhibited lower esophageal distensibility when compared to those with dysphagia alone, and that the need for follow-up dilation also correlated with lower distensibility.<sup>26</sup> Finally, studies have also shown that higher grades of ring severity, as graded using EREFS, correlated stepwise with reduced distensibility metrics.<sup>13,27</sup> The same study, however, found that severity of exudates, furrows, and degree of eosinophilia was not associated with distensibility parameters, which may be a reflection of the

inflammatory phenotype. Though not yet widely available, FLIP technology may play an important role in identifying adequate therapeutic goals, particularly in those patients with fibrostenotic phenotypes.

Other less invasive techniques have also been the focus of ongoing research, in attempts to identify tools for assessment of disease severity that do not require sedation and/or endoscopy. One such technology is the Cytospunge, an ingestible gelatin capsule comprising of compressed mesh attached to a string, which, in a small study of 20 patients, identified 11 of 13 patients with active EoE (defined at greater than 15 eosinophils/high power field) when compared to standard endoscopy.<sup>28</sup> Similarly, a swallowed esophageal string test has identified eosinophil-derived protein biomarkers in children with EoE.<sup>29</sup> Use of unsedated transnasal endoscopy has also been evaluated in both adult and pediatric populations, and has been found to be effective, lower-cost, and well tolerated by patients.<sup>30,31</sup> Finally, the use of esophageal brushings has been studied as a cheaper and more convenient alternative to esophageal biopsies, but has shown limited sensitivity and specificity for the detection of esophageal eosinophilia in a prospective study.<sup>32</sup>

## CONCLUSION

There have been significant advances in our understanding of the mechanisms that drive the inflammatory and remodeling consequences of EoE. We have learned that standardizing definitions has helped clinicians and researchers define adequate therapeutic goals, allowing for a common language to be spoken among physicians. Although not a part of the diagnostic criteria, endoscopic findings play a critical role in the global assessment of disease severity, and are often the first hint to a physician that a patient has EoE. Moreover, initial severity of endoscopic findings has important clinical implications with regard to treatment options, including the need for dilations and predicting the effectiveness of medical therapies. Finally, given the discord between patient-reported symptoms and histologic outcomes, endoscopic features may serve as a more reliable therapeutic marker. Therefore a comprehensive assessment of a patient's symptoms, histology, and endoscopic findings is critical in ascertaining a global assessment of a patient's disease phenotype to determine an adequate treatment plan.

## INTRODUCTION

Gastroesophageal reflux (GER) occurs when there is retrograde movement of gastric contents into the esophagus. It occurs primarily after meals, and is part of a normal venting process to prevent excessive gastric distension and dyspepsia (the so-called "burp or belch" reflex). In contrast, gastroesophageal reflux disease (GERD) is defined as an abnormally elevated frequency of reflux and/or volume of refluxate, and typically presents as troublesome symptoms including heartburn and regurgitation.<sup>1</sup> Other atypical and extra-esophageal symptoms like chest pain, cough, and hoarseness can also occur.<sup>2</sup> Although chronic, GERD is generally not progressive. The majority of patients with GERD will not manifest endoscopically identifiable mucosal damage; others may present with esophagitis, esophageal stricture, or Barrett's esophagus (BE).<sup>3</sup>

GERD is one of the most common diseases worldwide and, whereas its incidence has increased over time, its prevalence is unequally distributed across the world. There is a substantially higher burden of GERD in the United States and Europe than in Asia. Recent data (2014) demonstrate that typical GERD symptoms occurring at least once weekly can be found in up to 27.8% of individuals in Western populations, but only 7.8% of individuals in East Asian populations.<sup>4</sup> There are some data linking GERD to genetic factors, particularly within families, but there are no known genetic risk factors.<sup>5</sup> Rather, this discrepancy across populations is likely due to both environmental factors like *Helicobacter pylori* infection, as well as lifestyle and dietary discrepancies.<sup>6</sup> Nonetheless, GERD is a frequent cause for referral to the gastroenterologist, and accounts for billions of dollars of health care costs annually.<sup>7</sup>

## ETIOLOGY

The search for a single etiologic factor for the development of GERD has been met with frustration. Instead, GERD can be considered a multifactorial disease, and our understanding of its pathogenesis has evolved, and continues to evolve, over time.

Although it is clearly associated with exposure to gastric acid and pepsin, and occasionally worsened in the setting of esophageal dysmotility, the underlying mechanism of GERD relates to a disorder at the level of the gastroesophageal junction (GEJ).

The GEJ is comprised of several components, including the extrinsic skeletal muscle of the diaphragm, the intrinsic smooth muscle of the distal esophagus, and the angle of His created by the specialized gastric sling fibers and connective tissue that includes the phrenoesophageal ligament.<sup>8</sup> As early as 1956, Code et al described a high pressure zone between the esophagus and the stomach.<sup>9</sup> It became clear over time that this zone was actually the combination of two integral parts, which includes a 4 cm-long lower esophageal sphincter (LES) and a 2 cm-long portion of the crural diaphragm. The GEJ is the barrier to reflux, and the intraluminal pressure at this level is a measure of the antireflux barrier.<sup>10</sup>

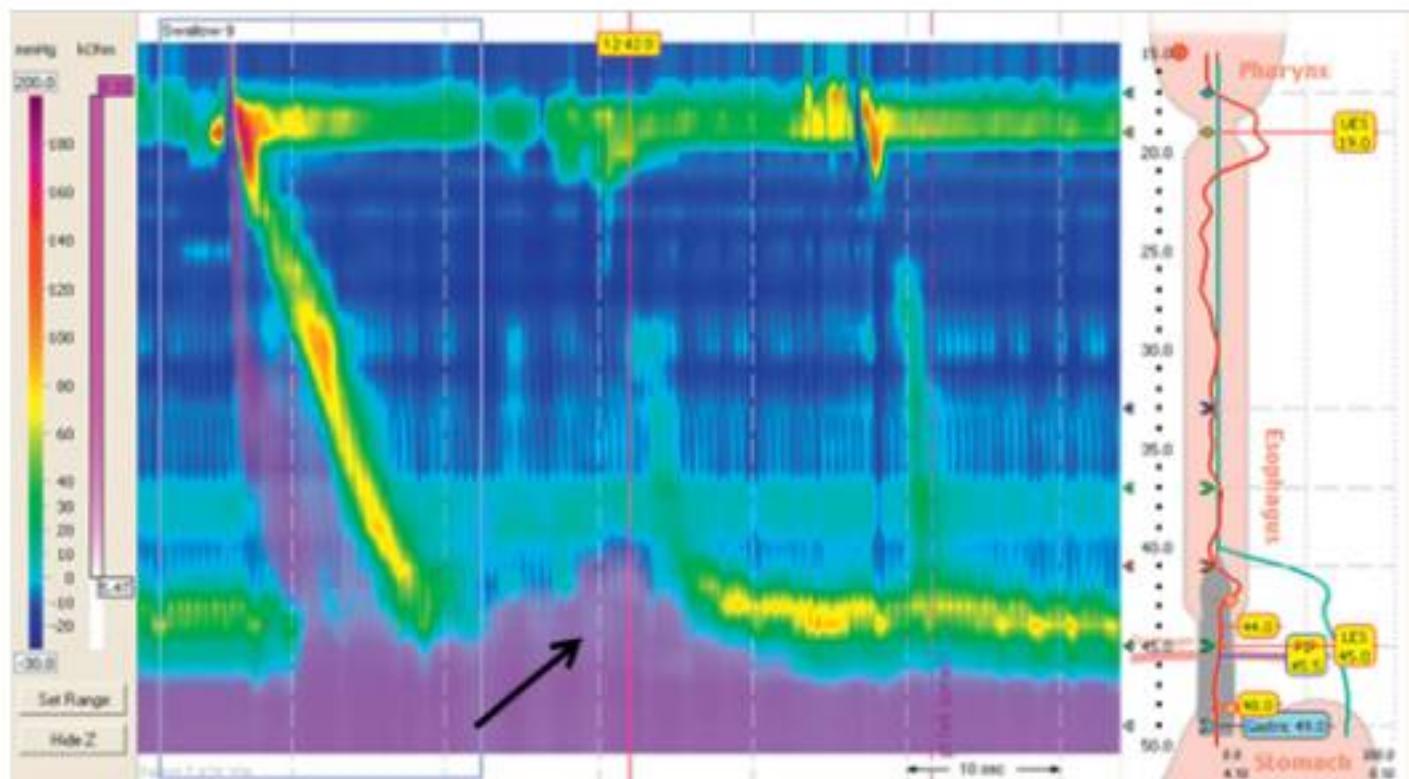

Although a low GEJ pressure and/or a dissociated GEJ region (such as occurs in patients with a hiatal hernia) permits GER if the gastric pressure rises higher than the GEJ resistance, a more important and far more common cause of GERD is transient relaxation across this barrier. In 1964, McNally et al described how belching is facilitated by LES relaxation, and in 1980, Dent et al reported on LES relaxation in reflux disease.<sup>11,12</sup> Transient lower esophageal sphincter relaxations (TLESRs) are a vagally mediated normal physiologic mechanism that facilitates the retrograde flow of gastric contents, including eructation and vomit, in the presence of gastric distension. However, in patients with GERD, TLESRs are the single most important mechanism underlying reflux, and they can be influenced by several factors.<sup>13</sup> During a TLESR, there is equalization of pressure between the stomach and esophagus, along with contraction of longitudinal esophageal muscle in a reverse peristaltic fashion (Fig. 24.1). TLESRs are increased during pharyngeal stimulation and with increasing gastric distension, both of which occur during the prandial and postprandial states, when most reflux events occur.<sup>14,15</sup> Patients with disordered sleep are at higher risk of GERD and, simultaneously, GERD increases the risk of disordered sleep in a positive feedback loop.<sup>16,17</sup> In contrast, the supine

**Abstract**

Gastroesophageal reflux is retrograde movement of gastric contents into the esophagus that occurs primarily after meals and is a normal physiologic process that prevents excessive gastric distension and dyspepsia. Gastroesophageal reflux disease (GERD) is defined as an abnormally elevated frequency of gastric reflux and/or volume of gastric refluxate, and typically presents as troublesome symptoms including heartburn and regurgitation. It is one of the most common diseases worldwide, and its incidence is increasing. Although the presence of hiatal hernia and esophageal dysmotility are important cofactors in reflux disease, transient lower esophageal sphincter relaxations (TLESRs) are the single most important mechanism underlying GERD. There are numerous tests available to aid in the diagnosis of GERD, but multichannel intraluminal impedance-pH (MII-pH) is the current gold standard. In patients with typical symptoms who improve with acid suppression, no further testing is necessary to confirm the diagnosis. Upper endoscopy should be obtained if symptoms do not improve with a trial of acid suppression or if "red flag" symptoms are present. Endoscopic findings of GERD include reflux esophagitis, peptic strictures and Barrett's esophagus, though many patients have normal esophageal mucosa. Management of GERD is usually medical, with proton pump inhibitors (PPIs) the initial therapy of choice for patients who experience symptoms at least twice a week. A Nissen fundoplication is an acceptable surgical alternative in patients with typical symptoms who are intolerant of PPIs. The most recent development in the treatment of GERD involves a surgically placed magnetic lower esophageal sphincter augmentation device.

position generally, and stable sleep specifically, can reduce the number of TLESRs.

The presence of a hiatal hernia also increases the frequency of TLSESRs, though this phenomenon alone does not explain the higher number of total reflux episodes in patients with GERD.<sup>19</sup> It is clear that a weakening of the GEJ is mechanically related to pathologic reflux in other ways as well. Having several constituent parts, in the normal state the GEJ can respond rapidly and dynamically to changes in both intraabdominal and intrathoracic pressures. In patients with a hiatal hernia, there is a relative or fixed dissociation between the LES and the crural diaphragm, limiting the capacity for preventing reflux. With an incompetent diaphragmatic component, gastric contents may flow more easily into the hernia sac and ultimately reflux into the esophagus across a weakened LES, especially during a TLESR.<sup>19</sup> As the hernia sac size increases, there is additional dilation of the esophageal hiatus, leading to further incompetence.<sup>20</sup> As expected, the severity of erosive esophagitis is predicted by hernia size and LES pressure.<sup>21</sup>

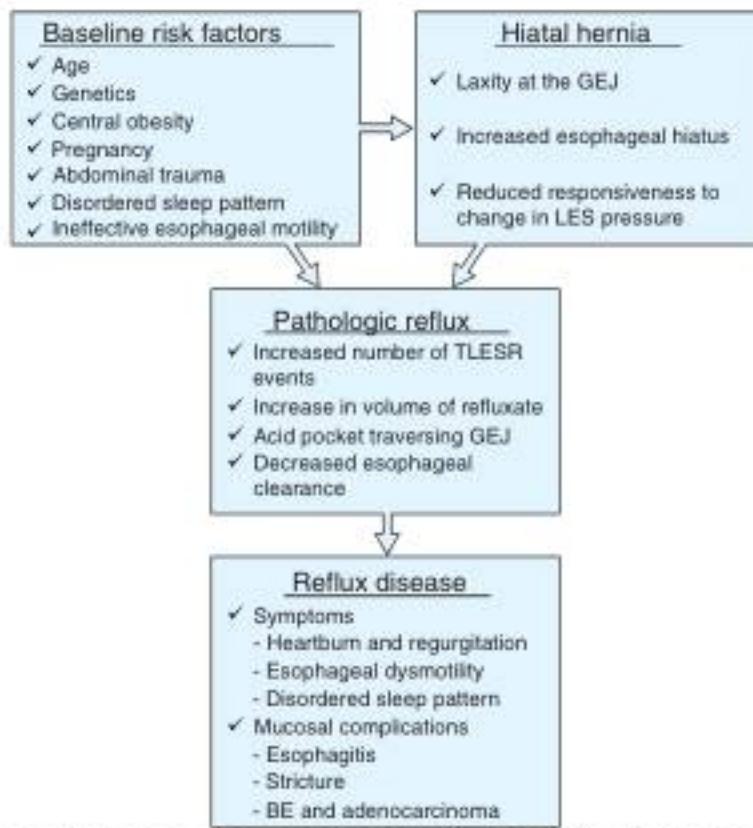

External factors that lead to hiatal hernia may therefore influence the presence of GERD. Instigating events causing an increase in intraabdominal pressure, like pregnancy, obesity, and trauma, are associated with the development of a hiatal hernia. Age, too, plays a role, as increased "wear and tear" results in loosening of the phrenoesophageal ligament.<sup>22</sup> Finally, there is evidence that the layer of highly acidic gastric juice in the postprandial proximal stomach (the so-called "acid pocket") also contributes to GERD.<sup>23</sup> The pH of this area is lower relative to the remainder of the gastric juices, which are buffered by the ingested food. Its clinical relevance was noted when GERD patients were shown to have longer acid pockets compared to healthy

patients due to the presence of hiatal hernia. When the acid pocket is located above the level of the diaphragm, as much as 85% of TLESRs are associated with reflux.<sup>24</sup>

Eventually, refluxed gastric contents are buffered, and must ultimately be cleared from the esophagus.<sup>25</sup> In patients with weak esophageal peristaltic strength (as determined by ineffective esophageal motility on high resolution manometry) there is reduced esophageal clearance capacity.<sup>26</sup> It is also possible that frequent reflux and pathologic acid exposure can in themselves lead to ineffective esophageal motility, thus creating another positive feedback loop contributing to GERD.<sup>27</sup>

A current conceptual model (Fig. 24.2) accounts for all these components that influence the development of GERD symptoms, as well as the mucosal changes or complications that are frequently associated with these factors. There are likely intrinsic and extrinsic factors that lead to a mechanically impaired GEJ and the development of a hiatal hernia, that both allow and cause increased frequency of reflux events and increased volume of refluxate. This cycle may cause ineffective esophageal clearance and lead to prolonged acid exposure, symptoms, and mucosal disease.

Injury to the esophageal mucosa is likely a multistep process. Experimental data demonstrate that repeated exposure to acid and pepsin in combination can lead to reduced distal esophageal motor contractions, reduced GEJ competence, and reduced compliance.<sup>28</sup> Although exposure to very high doses of acid alone may cause esophagitis, the addition of the proteolytic enzyme pepsin leads to an increasing degree of mucosal injury and permeability.<sup>29</sup> Although elevated acid exposure is correlated with the development of esophagitis, it is not a good predictor of the severity of the esophagitis or mucosal complications like BE.<sup>30</sup> Therefore other factors aside from acid and pepsin

**FIG 24.2** A conceptual model of gastroesophageal reflux disease. BE, Barrett's esophagus; GEJ, gastroesophageal junction; LES, lower esophageal sphincter; TLESR, transient lower esophageal sphincter relaxation. (Adapted from Boeckxstaens G, El-Serag HB, Smout AJ, et al: Symptomatic reflux disease: the present, the past and the future. Gut 63(7):1185–1193, 2014.)

alone are thought to be related to the development of GERD. Duodenogastroesophageal reflux (DGFR) of bile acids and pancreatic enzymes are both implicated in the development of GERD symptoms. The precise role of these components depends on whether the bile acids are conjugated or unconjugated; both of these processes occur in different pH environments.<sup>31</sup> DGFR and bile acids have a putative role in the development of BE and esophageal adenocarcinoma and may be associated with the development of symptoms in patients with nonerosive reflux disease (NERD).<sup>32</sup> Esophageal mucosa exposed to bile acids in acidic conditions develop dilated intercellular spaces (DISs), a marker of mucosal permeability that can be seen in patients with NERD.<sup>33</sup> Even in neutral pH environments, the pancreatic enzyme trypsin can damage the esophageal mucosa.<sup>34</sup>

Intriguing new evidence is further modifying our understanding of the pathogenesis of mucosal injury in GERD. In addition to acid and pancreaticobiliary reflux, a cytokine-mediated inflammatory cascade may prime the mucosa for injury from acid. As first reported in animal studies, acid exposure may trigger cytokine production, leading to lymphocytic infiltration that starts in the submucosa and progresses toward the epithelial surface. The corresponding inflammatory reaction may make later acid-mediated injury possible.<sup>35</sup> These findings have been reproduced in a small human tissue study.<sup>36</sup> Although preliminary, these data suggest that our understanding of the pathogenesis of GERD continues to grow, and further reveal the complex nature of this common disease.

## DIAGNOSIS

The diagnosis of GERD can be made clinically based on typical symptoms responding to treatment with acid suppression. Indeed, current guidelines recommend an empiric 4–8 week trial with acid-suppressive proton pump inhibitors (PPIs) for patients with typical symptoms, as well as for other common GERD presentations like dyspepsia or epigastric pain.<sup>37</sup> However, this approach is limited, as PPI trials show only 78% sensitivity and 54% specificity for accurately diagnosing GERD.<sup>38</sup> Therefore even in patients with typical symptoms, and especially in patients with atypical symptoms like cough, specific physiologic testing may be required to establish or confirm a diagnosis. Mucosal changes like erosive esophagitis (EE) or BE are the *sine qua non* of GERD, and no additional confirmatory testing is needed, but these findings are rather infrequent, and endoscopy is not considered necessary for the diagnosis of GERD in patients with typical symptoms.<sup>39</sup> In fact, esophagogastroduodenoscopy (EGD) would miss the presence of GERD in many patients, as the esophagus may appear completely normal despite the presence of symptomatic GERD.<sup>40</sup> Endoscopic findings can be characterized as signs of severe disease and are actually complications of GERD (the endoscopic evaluation of GERD is described further later). Although historically included as part of the diagnostic testing algorithm for GERD, barium esophagography findings do not correlate with the incidence or extent of reflux seen on physiologic testing.<sup>41</sup> Although

**TABLE 24.1 Symptoms and Complications of Gastroesophageal Reflux Disease**

Esophageal Symptoms	Extra-Esophageal Symptoms	Complications
Heartburn	Pulmonary reflux	Reflux esophagitis
Regurgitation	Asthma	Stricture
Chest pain	Cough	Barrett's esophagus
Dysphagia	Laryngeal reflux	Adenocarcinoma
	Globus	
	Throat clearing	
	Hoarseness	

potentially helpful in evaluating or excluding other causes of esophageal symptoms, barium esophagography has no role in diagnosing GERD.

### Symptoms

The symptoms of GERD should be classified as either typical or atypical, which correlate roughly with esophageal and extraesophageal symptoms, respectively (Table 24.1). Heartburn is a burning sensation in the retrosternal area, and regurgitation is the perception of flow of refluxed gastric contents into the mouth or hypopharynx.<sup>1</sup> In the United States, heartburn is more common than regurgitation (13.2%–25.2% vs. 6.3%–14.9%), and this same relationship also holds in Western Europe.<sup>4</sup> These typical symptoms respond better to acid-suppressive therapy than atypical symptoms, but even when they are the only symptoms present, they are not sensitive for the diagnosis of GERD.<sup>5</sup> Clinical evaluation alone is not good at predicting erosive esophagitis, with only 30%–76% sensitivity and 62%–96% specificity in the presence of typical symptoms.<sup>6</sup> However, in patients with typical symptoms who do respond to PPI therapy, no additional testing is needed.<sup>7</sup>

GERD can also manifest as chest pain, and it is thought to be a major cause of noncardiac chest pain syndrome.<sup>8</sup> Pulmonary symptoms like nonallergic asthma may also be attributed to GERD.<sup>9</sup> Complaints of chest pain, cough, or dyspnea in the absence of typical GERD symptoms warrant further diagnostic investigation (at least physiologic testing) after exclusion of primary cardiopulmonary disease. Dysphagia is also a possible presentation of GERD, especially if esophagitis is present, and is a red flag symptom that deserves initial endoscopic evaluation (discussed in further detail later).

The correlation between acid reflux and atypical, or extraesophageal, symptoms is less clear. Patients with atypical symptoms frequently present to otorhinolaryngologists.<sup>10</sup> However, only 54% of patients diagnosed with laryngoesophageal reflux disease (LERD) have abnormal acid exposure (confirming a diagnosis of GERD), despite up to 93% of patients with posterior laryngeal inflammation having symptoms.<sup>11</sup> As such, these complaints are less responsive to acid suppression or antireflux surgery.<sup>12</sup> Prolonged trials of even high (off-label) doses of acid suppressors have not shown a benefit for empiric therapy in this population.<sup>13</sup> Recent data (2016) demonstrate no ability to distinguish between healthy subjects and those with laryngoesophageal symptoms using salivary pepsin and oropharyngeal reflux testing.<sup>14</sup>

### Endoscopy

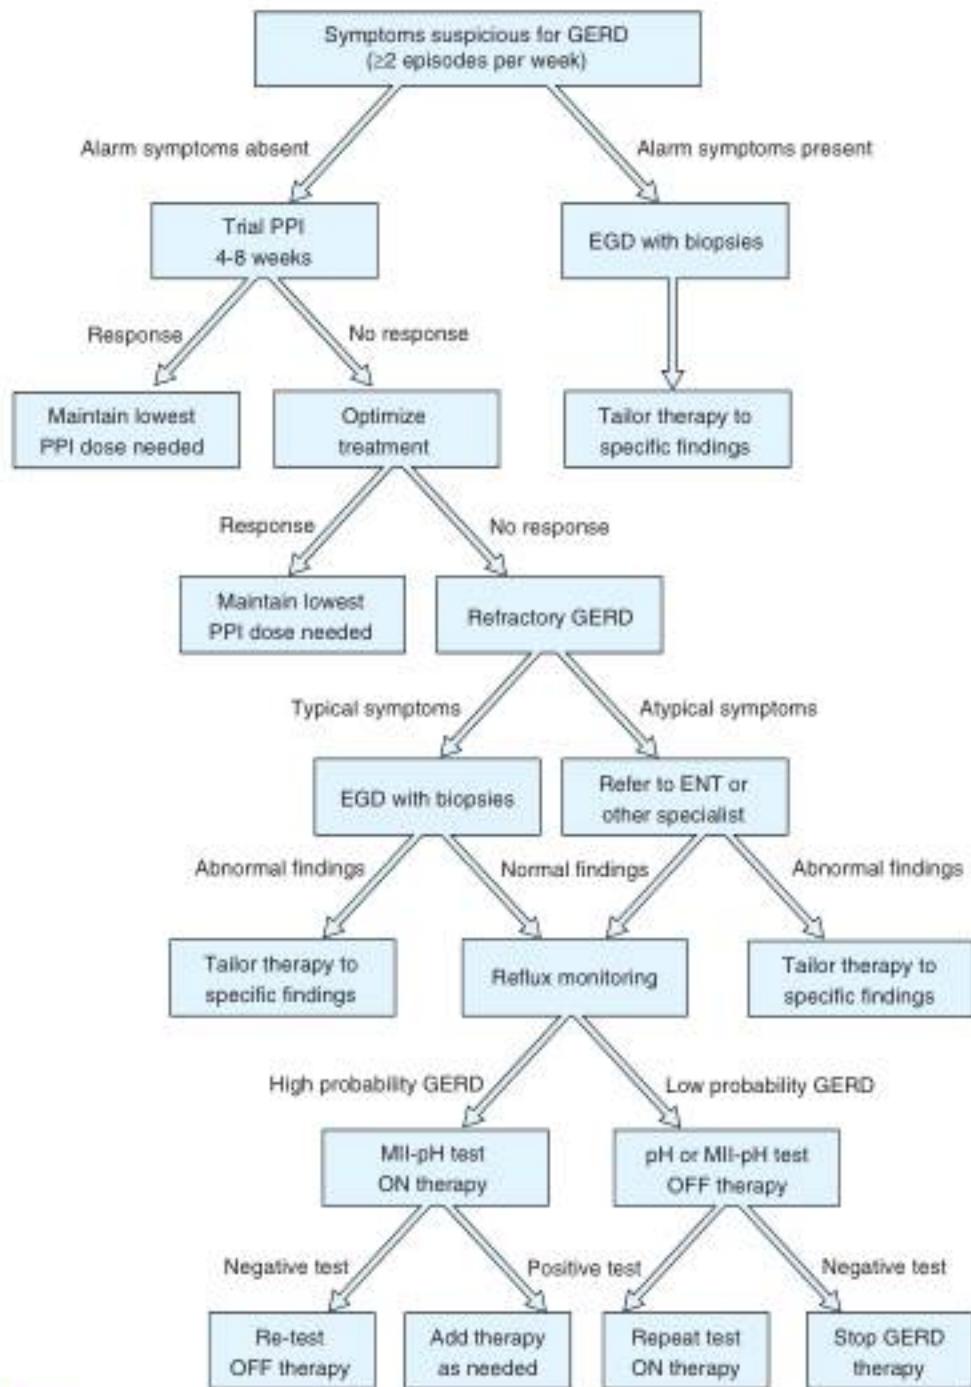

EGD diagnostic testing is not recommended initially for GERD symptoms unless red flag signs are present.<sup>15</sup> In fact, EE will only be present in approximately one-third of patients with reflux

symptoms, and only 20%–60% of patients with abnormal reflux testing, which therefore limits its utility.<sup>16</sup> Instead, EGD should be used to avoid misdiagnosing patients who have failed initial therapy or to identify and/or treat patients with complications of GERD. The role of endoscopy in patients with GERD, therefore, is limited to the evaluation of those patients with persistent symptoms despite adequate PPI therapy, those who have multiple risk factors for BE because of its premalignant nature, those who require pre- or postoperative evaluation for antireflux procedures, or those with symptoms (especially dysphagia) suggestive of complicated disease (Fig. 24.3).<sup>17</sup> Patients who fail to respond adequately to empiric PPI therapy should be counseled regarding how best to take their PPI therapy to optimize the trial before EGD is considered, and in those who respond to PPIs, the lowest effective PPI dose should be sought for chronic administration to limit the potential for long-term side effects of therapy.<sup>18</sup> In addition, consideration should be given to pulmonary or otorhinolaryngology (ENT) evaluation in patients with atypical symptoms prior to resorting to EGD because atypical manifestations of GERD are often confounded with other more common non-gastrointestinal conditions, such as asthma, postnasal drip, or allergies.<sup>19</sup> If ENT and/or pulmonary evaluation fails to identify an alternative cause for the symptoms, EGD often fails to identify any abnormalities, so many authorities will often forego EGD altogether and proceed directly to pH testing instead.<sup>20</sup> However, EGD should always be considered, especially in young males with dysphagia, in order to distinguish GERD from eosinophilic esophagitis (EoE) or PPI-responsive eosinophilia; this should generally be done in the presence of PPI therapy to permit exclusion of the latter condition.<sup>21</sup>

There are multiple endoscopic findings that can occur in GERD. Early changes include edema and friability.<sup>22</sup> These are nonspecific findings, but in the presence of persistent acid exposure, erosions can develop that are characterized by shallow mucosal breaks. These usually occur at the squamocolumnar junction (SCI) and extend proximally. Identified as linear streaks extending from and/or present between the folds, these erosions are often bordered by white exudate and erythema. In severe cases, there may be ulceration, but this finding is not pathognomonic for GERD, and may also be seen in infectious, pill-induced, or stasis esophagitis.<sup>23</sup> In addition to revealing normal mucosa or EE, the endoscopic appearance of the esophagus may mimic other disorders. Most importantly, there can be substantial overlap between the appearance of GERD and EoE, including with the presence of so-called ringed or feline esophagus.<sup>24</sup> Late findings of chronic reflux include peptic strictures, BE, and esophageal adenocarcinoma.<sup>25</sup> Schatzki, or type B, rings are always associated with a hiatal hernia and mark the inferior margin of the esophagus; they can also be seen in conjunction with GERD, although a direct correlation is controversial.<sup>26</sup> The endoscopic findings and management of these topics are discussed in detail in Chapters 21, 25, and 27.

Several endoscopic grading systems have been developed to standardize reporting and interpretation of endoscopic findings of GERD (Table 24.2). In Europe, the Savary-Miller schema has been favored, whereas the most commonly used method in the United States is the Los Angeles (LA) Classification (Fig. 24.4).<sup>27,28</sup> In Japan, a modified version of the LA grading scale is sometimes used that includes normal mucosa as well as minimal changes, although there is poor inter-rater reliability with milder findings of esophagitis.<sup>29</sup>

In typical EE, endoscopic tissue sampling is generally not indicated. Routine biopsies of normal tissue may reveal basal

**FIG 24.3** A proposed diagnostic approach for the management of symptoms of gastroesophageal reflux disease (GERD). In this schema, the use of multichannel intraluminal impedance-pH (MII-pH) probes on or off proton pump inhibitor (PPI) therapy in patients who remain undiagnosed despite a trial of empiric PPI therapy and esophagogastroduodenoscopy (EGD) or targeted specialist referral is determined by the type of presenting symptom complex. ENT, otolaryngology. (Modified from Katz PO, Gerson LB, Vela MF. Guidelines for the diagnosis and management of gastroesophageal reflux disease. *Am J Gastroenterol* 108[3]:308–328, 2013.)

cell hyperplasia, papillary elongation, and DIS.<sup>60</sup> In the setting of inflammation, a neutrophilic and/or eosinophilic infiltrate may be present. None of these histologic findings are sensitive or specific for GERD.<sup>61</sup> Therefore the main indications for tissue sampling are to exclude EoE in patients with reflux despite therapy, confirm the presence of BE, or exclude infectious etiologies. All

these topics, including specific sampling techniques, are discussed in further detail in Chapters 23 and 25.

Although an esophageal capsule endoscopy device has been developed, its performance compared to standard endoscopy for diagnosing esophagitis, hiatal hernia, and BE is poor, and therefore it has not gained widespread clinical use.<sup>62,63</sup>

**TABLE 24.2 Endoscopic Grading Schemes for Esophagitis**

Modified Los Angeles Classification	
Grade N	Normal mucosa
Grade M	Minimal changes to the mucosa (such as erythema)
Grade A	One or more mucosal breaks < 5 mm in length, confined to folds
Grade B	One or more mucosal breaks > 5 mm in length, confined to folds and not continuous between folds
Grade C	Mucosal breaks between folds, but affecting < 75% of luminal circumference
Grade D	Mucosal breaks between folds, but affecting > 75% of luminal circumference
Savary-Miller Classification	
Grade 0	No esophagitis
Grade I	Single erosion on one longitudinal fold
Grade II	Multiple erosions on multiple folds
Grade III	Circumferential erosions
Grade IV	Ulcer, stricture, or short esophagus with or without Grades I-III
Grade V	Barrett's esophagus with or without Grades I-III

## Esophageal pH Testing

There are several physiologic tests currently available to aid in the diagnosis of GERD. Because up to 40% of patients with GERD symptoms have no endoscopic evidence of reflux, these tests can be helpful to "rule in" patients with NERD, as well as to exclude those patients with esophageal hypersensitivity or functional heartburn if medical therapy and EGD have both been nondiagnostic.<sup>3,14</sup>

Catheter-based testing includes both pH-only probes and multichannel intraluminal impedance-pH testing (MII-pH). Reflux testing has evolved since 1960, when Tuttle et al developed a glass tube probe to identify a pH gradient between the esophagus and the stomach.<sup>15</sup> Initial catheters were cumbersome, until DeMeester et al (1974) created a device with an external electrode, though even this test still required hospitalization.<sup>16</sup> More practical means of outpatient ambulatory testing became available in the 1980s.

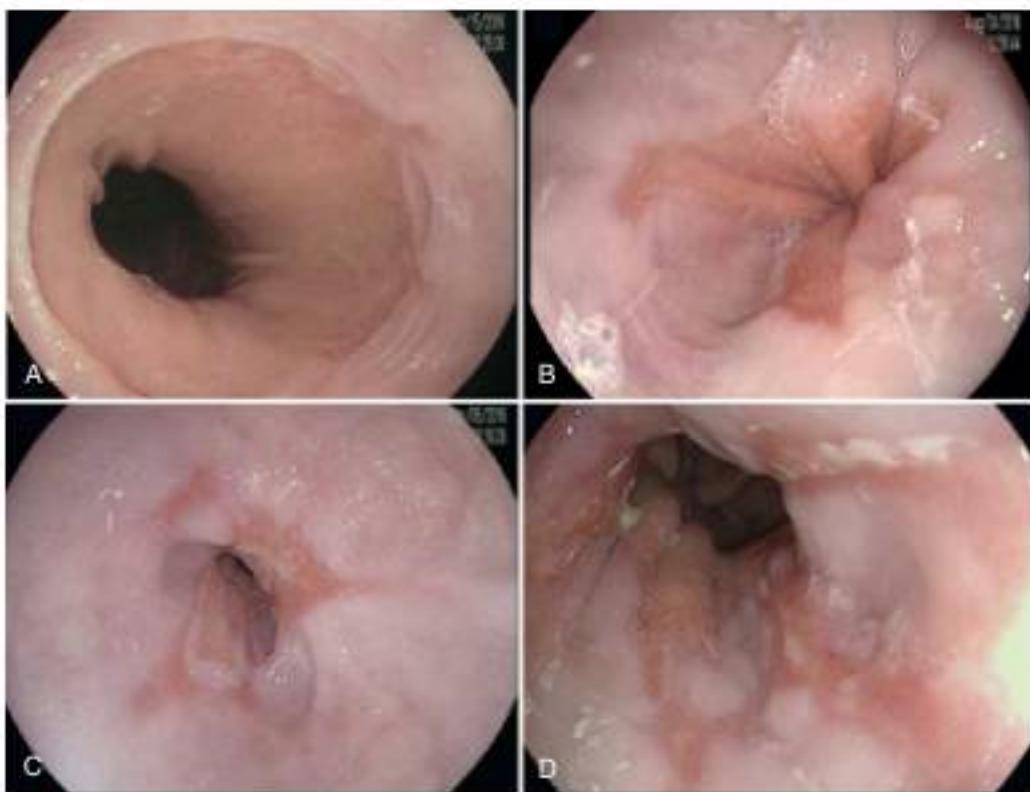

Current reflux testing takes advantage of the same principles. In pH-only probes, a catheter with one to three electrodes along the catheter length is passed transnasally through the esophagus into the stomach. The reference electrode is located 5 cm proximal to the LES, which is typically identified first by manometry and, if present, additional probes can be placed higher in the esophagus (usually 10–15 cm proximally) to evaluate for proximal reflux, or lower into the stomach (usually 15 cm below the reference electrode) to evaluate therapeutic efficacy. Patients usually keep this probe in place for 24 hours and are instructed to carry out their normal activities without restrictions other than bathing (which can damage the probe), exercising vigorously (which can dislodge the probe), and ingestion of acidic substances such as wine (which can lead to false positive results). Patients are also

asked to maintain a log or diary of their position (upright or supine), eating, medication administration, and symptoms during monitoring, the latter to provide a measure of the correlation of reflux events with symptoms.<sup>17</sup>

Although useful, catheter-based pH testing has a disadvantage in that it may discourage patients from performing their usual activities during the study period because of discomfort and/or aesthetic concerns.<sup>18</sup> A significant development occurred with the introduction of the Bravo wireless pH monitoring system (Medtronic, North Haven, CT). Compared to patients undergoing catheter-based testing, patients using the Bravo system have fewer nasopharyngeal side effects and are more likely to perform usual daily activities like going to work, sleeping, and eating, thereby more closely matching their general activities during reflux events.<sup>19</sup> Although not required, this system is often deployed in conjunction with endoscopy to help identify the SCJ so that accurate manometric identification of the proximal border of the LES is not required (Fig. 24.5). When the capsule is placed endoscopically, it is attached to the esophageal mucosa 6 cm above the SCJ (which correlates closely with the proximal border of the LES) and deployed using a specialized delivery system that includes a vacuum pump and firing pin. Less discomfort and fewer migrations occur with this device compared with catheter-based systems. Additionally, Bravo monitoring allows for prolonged monitoring for 48–96 hours, and even permits "on" and "off" therapy periods of monitoring to potentially improve the sensitivity and specificity of testing.<sup>20,21</sup>

Nonetheless, both catheter and wireless pH tests only provide information on esophageal acid exposure. In contrast, MII-pH probes allow for the detection of acid as well as intraluminal bolus presence. This technique was first described by Silny in 1991, and is based on the principle of measuring the difference in the electrical conductivity of air and liquid.<sup>22</sup> With the addition of multiple impedance sensors spaced several centimeters apart along the length of the catheter, it is possible to determine the presence of liquid versus air and its direction of flow.<sup>23</sup> As a result, one can determine if acid or nonacid refluxate is present. As with the pH-only probe, though, this test is limited by duration, the presence of an indwelling catheter, and accurate patient-reported symptoms. Nonetheless, this technique correlates well with barium studies and manometry to confirm bolus movement, and is considered the most sensitive tool for detecting GERD independent of refluxate acidity.<sup>22,24</sup> In addition, MII-pH testing can arguably also be performed in patients on antisecretory therapy to distinguish incompletely treated GERD from GERD-like symptoms arising from another cause (see Fig. 24.3).

Normative data exist for pH and reflux testing to aid in the diagnosis of GERD. The exact cutoff values may vary depending on the center, but the most relevant parameter is esophageal acid exposure, i.e., the time for which the pH is less than 4.0 at a reference point located 5 cm above the LES.<sup>25,26</sup> This value reliably correlates with the presence of heartburn in patients with GERD, and it is also an excellent way to differentiate between patients with EE or BE and those with NERD.<sup>27</sup> Several other variables can be identified with combined impedance/pH testing, including the total number of reflux episodes, esophageal acid clearance times, and composite indices like the DeMeester score. Additional symptom association analyses have been devised to predict the likelihood that reported symptoms are related to GERD. The most straightforward to calculate is the symptom index (SI). This is determined by dividing the number of reflux-related symptoms by the total number of symptoms reported and multiplying by

**FIG 24.4** Los Angeles (LA) Classification. Clockwise from the top left: **A**, LA A (one or more mucosal breaks < 5 mm in length, confined to folds). **B**, LA B (one or more mucosal breaks > 5 mm in length, confined to folds and not continuous between folds). **C**, LA C (mucosal breaks between folds, but affecting < 75% of luminal circumference). **D**, LA D (mucosal breaks between folds, but affecting > 75% of luminal circumference). (From Lundell LR, Dent J, Bennett JR, et al: Endoscopic assessment of oesophagitis: clinical and functional correlates and further validation of the Los Angeles classification. Gut 45[2]:172–180, 1999.)

100. If the SI value is greater than or equal to 50%, it is considered positive, with greater than 90% sensitivity and over 70% specificity.<sup>70</sup> Fig. 24.5 demonstrates a symptom-associated acidic reflux event identified by MII-pH testing. Unfortunately, there are scant data correlating the SI, or other symptom association scales, with outcomes in patients who have failed a PPI trial.<sup>71</sup>

Substantial debate also exists over whether testing should optimally be done on or off PPI therapy. Although many factors may influence baseline normal levels, there are standard ranges for abnormal acid exposure on and off acid suppression.<sup>30,31</sup> The esophageal acid exposure is lower with a wireless pH probe, and may justify a modified threshold, but there is very good concordance between this and catheter-based pH testing.<sup>32</sup> Current guidelines recommend that the decision to test on versus off therapy should be based on the pretest probability of GERD. Specifically, patients with a low likelihood of GERD should be evaluated off therapy, whereas a test should be done on PPI if there is a high likelihood of GERD.<sup>72</sup>

Although all forms of current reflux monitoring are reliable in patients with erosive esophagitis, in patients with nonerosive disease, or who are at least endoscopy negative, both sensitivity and specificity are decreased.<sup>33</sup> This creates a clinical conundrum because patients with EE are most likely to have typical symptoms and least likely to need confirmatory testing. As a result, direct mucosal impedance measurement has gained increasing attention, particularly for patients with NERD. Traditional reflux testing

provides data over only a short study period, and due to the brief study duration, there is the possibility of missed events or false negative results. Directly measuring mucosal impedance attempts to evaluate chronic mucosal changes, and is theoretically more sensitive. The basis for this approach is the DISs that are known to be present within the esophageal mucosa. This finding occurs even in the absence of esophagitis, and it may be a marker for chronic GERD.<sup>34</sup> The presence of DISs leads to increased permeability in animal models, and may be measured using a through-the-scope catheter to evaluate impedance between two points along the esophageal mucosa.<sup>35</sup> Compared to wireless pH monitoring, direct mucosal impedance had superior positive predictive value (96% vs. 40%) for identifying GERD patients<sup>36</sup> in the limited number of studies that have been performed to date. This represents an exciting development in GERD testing and warrants further study.

## TREATMENT

Medical acid suppression remains the cornerstone of GERD treatment. As discussed previously, patients with typical symptoms or EE on endoscopy demonstrate the best response to acid inhibition. In those patients with atypical symptoms or those who fail to respond to initial therapy, adjunctive therapies like lifestyle modification, including weight loss and smoking cessation, are recommended.<sup>37</sup> Elevating the head of the bed and avoiding late night eating is effective in patients with nocturnal GERD.<sup>37</sup>

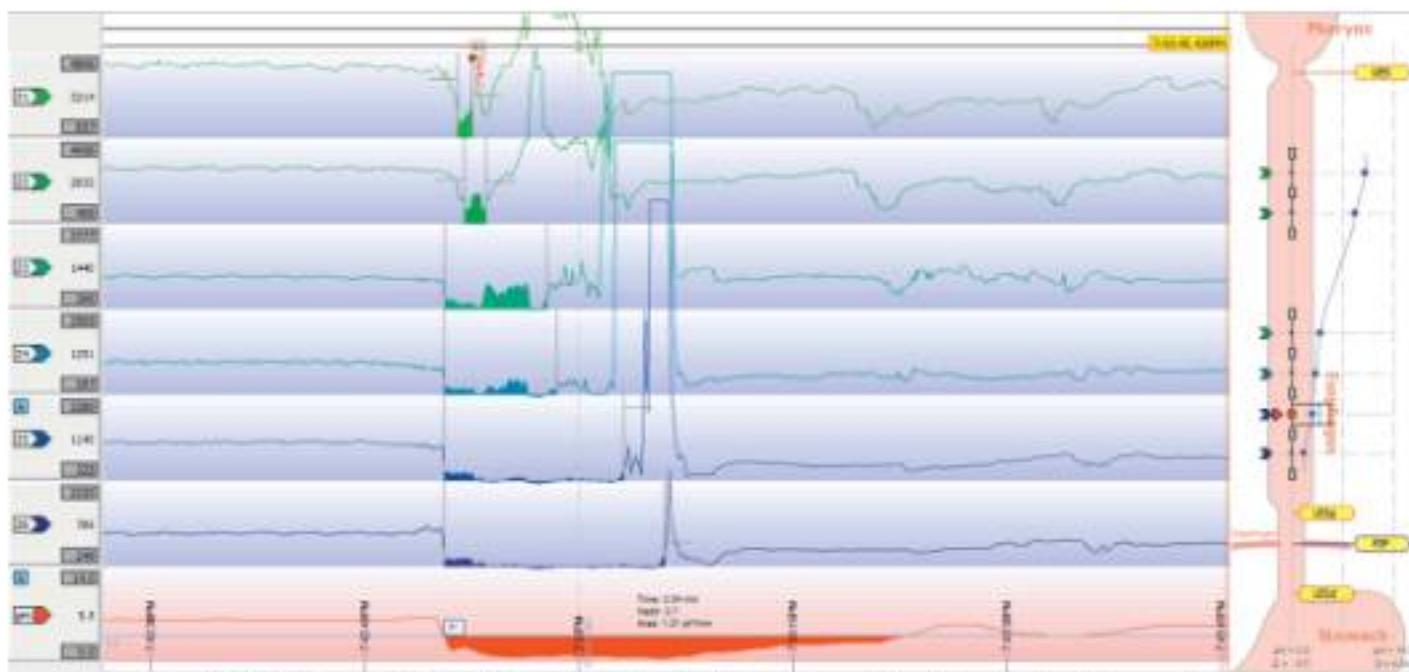

**FIG 24.5** Endoscopic confirmation of proper placement of the Bravo (Medtronic, North Haven, CT) pH monitoring system approximately 6 cm proximal to the squamocolumnar junction, which correlates closely with the proximal border of the lower esophageal sphincter (LES).

Atypical symptoms often prove more difficult to resolve, and can require combination therapy with other agents. In patients requiring long-term medical therapy for complete symptom control, particularly those with typical symptoms responsive to PPIs but unwilling to take them long term, traditional antireflux surgery remains an option. The laparoscopically placed LINX device (Torax Medical, Shoreview, MN) is another Food and Drug Administration (FDA)-approved option for patients who continue to experience GERD symptoms despite maximum medical therapy.<sup>88</sup> Emerging endoscopic technologies such as the transoral incisionless fundoplication (TIF) have received substantial interest as possible nonoperative procedural interventions for GERD.

### Medical Management

Prior to the approval of PPIs, histamine-2 receptor antagonists (H2RAs) were the most potent therapies available for GERD management.<sup>89</sup> Traditional antacids like calcium carbonate do not provide any long-term benefit for patients with GERD. In contrast, H2RAs are superior to placebo and are effective in the management of mild, intermittent GERD (with symptoms occurring 1 day or less per week). Unfortunately, tachyphylaxis can occur with this class of medications, and therefore they have relatively limited utility in patients with chronic moderate to-severe GERD (with symptoms occurring 2 or more days per week).<sup>90</sup>

However, in the modern era, the mainstay of medical therapy for GERD is PPI therapy. These drugs were initially developed in the 1980s, and omeprazole, first approved by the FDA for the treatment of Zollinger-Ellison Syndrome, was initially marketed in the United States in 1989.<sup>91</sup> Since that time, three additional

**FIG 24.6** Tracing of a multichannel intraluminal impedance with pH testing. In this example, there is excellent symptom correlation with chest pain recorded by the patient during the acid reflux event. *LES*, lower esophageal sphincter; *PIP*, pressure inversion point; *UES*, upper esophageal sphincter.

compounds and two enantiomers have become available that are currently indicated for healing and maintenance of EE, as well as treatment of GERD symptoms.<sup>92</sup>

Antisecretory therapy with PPIs targets the final common pathway for acid secretion into the gastric lumen. PPIs effectively and consistently raise intragastric pH and decrease gastric acid secretion.<sup>93</sup> In these ways, PPIs reduce both the acid content and volume of gastric refluxate. All PPIs are superior to H2RAs for healing of EE, as well as for treatment of nonerosive disease.<sup>94,95</sup> For maximum efficacy, it is recommended that all delayed-release PPIs should be taken 30–60 minutes prior to meals<sup>21</sup> (with the exception of dexlansoprazole and omeprazole–sodium bicarbonate combination therapy). Although a common cause of failing to respond to PPI therapy is incorrect dosing administration,<sup>96</sup> GERD is chronic, and symptoms are likely to recur after discontinuing medical therapy, even when PPIs have been used correctly.<sup>97</sup> There are no significant differences between PPIs that warrant switching medications in patients with inadequate response to one PPI.<sup>97</sup>

Although these drugs have been available and used safely for several decades, there are now numerous reports of potential side effects. In addition to pathologic bone fractures, idiosyncratic electrolyte disturbances, and renal injury, more recent data (2016) have shown long-term PPI treatment to be potentially associated with micronutrient deficiencies, infections, cardiovascular disease, and dementia.<sup>98</sup> The studies that generated these alarms are retrospective and correlational in nature, but have generated substantial concern among patients. As a result, in addition to using the lowest effective doses of PPIs for adequate GERD symptom management, alternative therapies can be considered alone or in combination with traditional PPI treatment.<sup>99</sup> Among these alternatives are alginate-based medications, which are often combined with typical antacids. These medications treat GERD via a unique mechanism by creating a mechanical barrier that displaces the postprandial acid pocket.<sup>100</sup> They are superior to both placebo and antacids in treating symptomatic GERD.<sup>100</sup> Although further studies are needed, this represents a potentially attractive option as an adjunctive therapy in patients who respond incompletely to PPI therapy, particularly as it relates to the acid pocket.<sup>101</sup>

Another medical alternative to PPIs is a novel class of medications called potassium competitive acid blockers (PCABs). These drugs are neither acid-activated nor affected by genetic variants, which are both drawbacks of PPIs; they also have very rapid onset and offset, which may allow for as-needed (i.e., PRN) usage even for more severe forms of GERD.<sup>102</sup> Their use in GERD may be an area of future investigation, although initial trials did not reveal improved symptomatic management of NERD or healing of EE compared to traditional PPIs.<sup>103,104</sup> Moreover, PCABs are extremely potent inhibitors of acid production, leading to higher gastrin levels than occur with PPIs, and there may be some safety concerns regarding this effect if therapy use is prolonged. Therapies that target other pathways involved in the development of GERD are also available. Baclofen, which effectively decreases TLESR frequency and increases LES pressure, has shown some clinic benefit, but is not FDA-approved for treatment of GERD.<sup>105</sup> Prokinetics like metoclopramide have a limited role and only in patients with evidence of delayed gastric emptying.<sup>106</sup> There are multiple other compounds under investigation that aim to modulate pain perception or provide mucosal protection.<sup>107</sup>

### Surgical Treatment

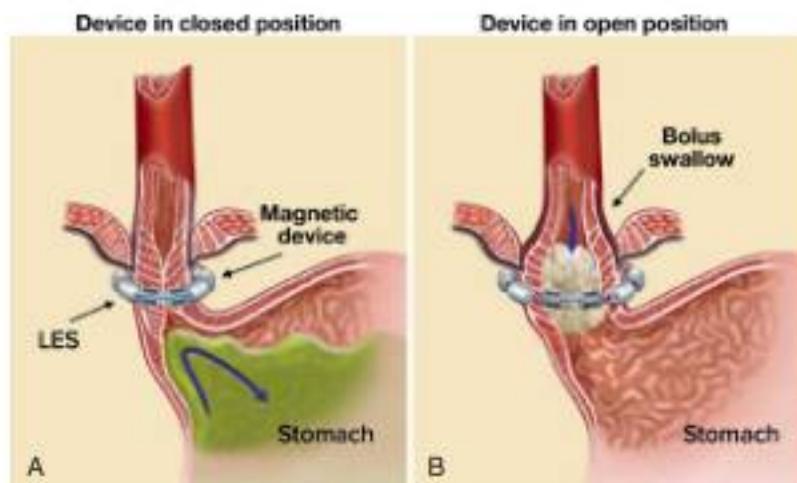

Historically, the primary alternative to treatment with acid suppression has been surgical treatment by gastric fundoplication.

Reproducing a functioning antireflux barrier by wrapping the LES with the proximal stomach was first described by Nissen in the 1950s.<sup>108</sup> His approach has undergone several iterations since that time, including modifications to the degree of wrap (e.g., 270-degree posterior, or Toupet, fundoplication). Enthusiasm for performing antireflux surgery, on the other hand, has waxed and waned. The number of antireflux surgical procedures performed in the United States has varied dramatically over the last several decades, often in response to the availability of new medications and concerns over cancer risks associated with GERD, as well as side effects from antireflux surgery.<sup>109</sup>

The Nissen fundoplication, as originally described, required an open incision and substantially longer hospitalization time than its modern iteration. The laparoscopic Nissen approach gained popularity in the early 1990s, but it was around this time that a randomized control trial demonstrated superior efficacy of open Nissen in controlling GERD than H2RA medical therapy.<sup>109</sup> Importantly, this study compared an open surgical procedure to treatment with H2RAs at a time when the laparoscopic approach had already been reported and PPIs were already available. Long-term follow-up data from this same cohort demonstrated no significant differences between the groups with respect to esophagitis, need for subsequent antireflux surgery, or satisfaction with their antireflux therapy.<sup>110</sup> The accompanying video (Video 24.1) discusses the endoscopic appearance of a surgical Nissen fundoplication.

It has become clear that carefully selected patients (those with typical symptoms who have responded to PPIs) are most likely to benefit from antireflux surgery.<sup>111</sup> Indeed, the laparoscopic approach has also been demonstrated to be superior to open surgery, with similar treatment outcomes and fewer complications.<sup>112</sup> This approach results in more durable long-term healing of esophagitis compared to PPIs, and fewer patients need PPIs after surgery, though remission rates are high in both groups.<sup>110,113,114</sup> Nonetheless, patients undergoing antireflux surgery risk perioperative complications that include death, and face other side effects like dysphagia, gas-bloat syndrome, disruption of the fundoplication, as well as unmet expectations.<sup>115</sup> On balance, there is general equivalence between these approaches for patients with typical symptoms, with surgery being favored for patients with volume regurgitation and intolerance of PPIs. In patients with GERD as a complication of morbid obesity, however, Roux-en-Y gastric bypass provides symptomatic improvement and is the preferred operative approach.<sup>116</sup>

The most recent surgical advance is magnetic LES sphincter augmentation using the LINX (Torax Medical) device. Composed of a circle of magnetic iron beads enclosed in a titanium case and connected by titanium arms, this is a laparoscopically-placed antireflux device (Fig. 24.7). It fits around the outside of the esophagus and, through magnetic forces, provides baseline LES sphincter augmentation that also accommodates the passage of food aborally and retrograde belching or vomiting. Developed by Ganz and colleagues, this device aims to provide a physical antireflux barrier without the troublesome side effects of migration or new onset bowel symptoms.<sup>117</sup> First described in 2008, this device now has longer-term safety and efficacy. Use of the device appears to result in significant and durable improvement in symptomatic response and a decreased need for medical acid suppression, and there have been no device migrations, erosions, or malfunctions reported in the device trials; however, postmarketing and surveillance data do demonstrate that these adverse events have occurred.<sup>118</sup> Symptoms that have often discouraged referral

**FIG 24.7** Diagrammatic representation of the LINX device (Torax Medical, Shoreview, MN). **A**, in the closed position (providing baseline resistance to reflux of gastric contents) and **B**, in the open position (accommodating for the passage of ingested material into the stomach). LES, lower esophageal sphincter. (From Ganz RA, Edmundowicz SA, Taiganides PA, et al: Long-term outcomes of patients receiving a magnetic sphincter augmentation device for gastroesophageal reflux. *Clin Gastroenterol Hepatol* 14(5):671–677, 2016.)

to surgery, including gas-bloat and dysphagia, occurred in 8.3% and 6% of patients, respectively, at five years.<sup>110</sup> These data are intriguing, but to date, no randomized controlled trials have been conducted comparing the device to traditional surgery or medical acid suppression. Current procedures have been conducted only in patients with small hiatal hernias (< 3 cm) and without esophageal dysmotility; therefore the data may not be generalizable, and it remains to be seen whether there is a specific patient for which this operation is ideal.

### Emerging Treatments

As neither surgery nor PPIs satisfactorily treat all GERD patients, there remains a strong incentive to develop alternative therapies. Endoscopic therapy is highly effective for many complications of GERD, and remains appealing as a potential therapeutic avenue for treating GERD itself. Such therapy should be safe, effective, and easy to apply. Multiple endoscopically placed devices and sphincter augmentation injectates have been developed over the last several decades. However, these have been troubled by serious adverse events, and currently there are no such devices available for use.<sup>111</sup> The Stretta technique, which involves the delivery of radiofrequency energy across the LES via a balloon-based array, has been advocated by surgical societies.<sup>112</sup> However, the data supporting such an approach are mixed. The exact mechanism by which this treats GERD patients is unclear, but is thought to be through a combination of provoking a local fibrotic process and disrupting the neural feedback pathway to blunt the noxious sensory response. Unfortunately, a systematic review and meta-analysis demonstrated no significant change in LES pressure, need for PPI use, or occurrence of GERD symptoms overall.<sup>112</sup>

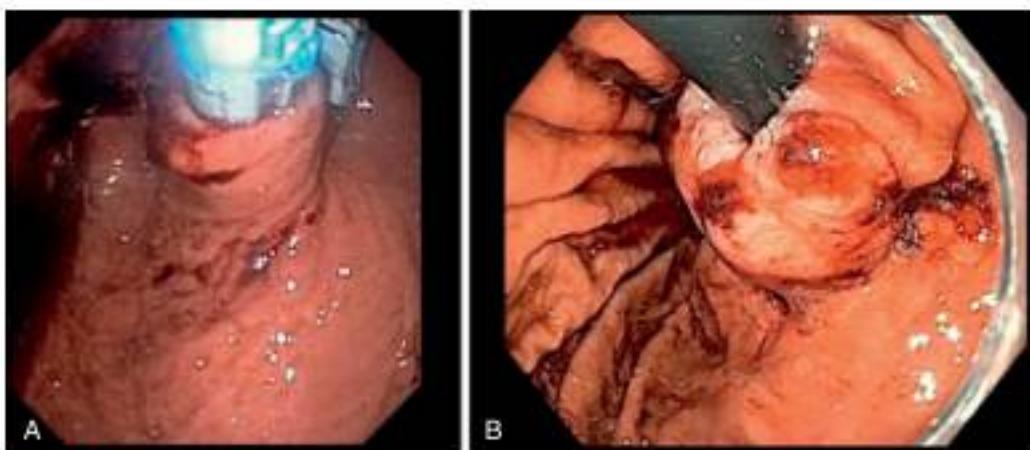

An alternative approach has been to endoscopically recreate an antireflux barrier. Two endoscopic fundoplication devices are undergoing development and study. The concept of endoscopic suturing dates to the 1980s, but has improved over time. TIF has yielded equivocal results. This technique uses a device that is advanced over an endoscope into the stomach. It is composed of several components that bring gastric tissue into abutment with

the esophageal lumen, after which H-shaped fasteners are deployed to create a valve-shaped antireflux barrier (Fig. 24.8).<sup>113</sup> Use of this device is associated with temporary improvements in pH scores, but its durability is less clear.<sup>114</sup> Importantly, a randomized controlled trial comparing TIF to PPIs did show improvement in regurgitation symptoms.<sup>115</sup> The patients selected were highly restricted, and could not have a hiatal hernia larger than 2 cm. Nonetheless, regurgitation is the main symptom that would otherwise prompt surgical fundoplication and, although these data need to be replicated, TIF might be a potential future substitute for laparoscopic fundoplication in some patients. Fewer data are available for another endoscopic fundoplication system that uses ultrasound guidance for the deployment of an endostapler. A relatively small study did demonstrate improvement in symptom scores and the need for PPIs, but these data only reflected a short follow-up interval.<sup>116</sup> Endoscopic fundoplication is an exciting prospect, but currently only preliminary data exist, and these need to be recreated and demonstrated over a longer timeframe prior to more widespread use of either of these techniques.

In the future, additional therapeutic options may include surgically implanted electronic LES pacing with the EndoStim system (EndoStim, The Hague, Netherlands). Although no randomized control trial data are available yet, there are uncontrolled data to support improvement in symptoms and a decreased need for medical therapy.<sup>117</sup> This approach has the possible advantages of having a minimal impact on the underlying anatomy and potentially being reversible.

### Treatment Summary

The primary and initial long-term treatment modality for patients with GERD is acid suppression with a PPI at the lowest effective dose. However, some of these patients will be inadequately controlled, and alternative therapies can be considered. Antireflux surgery with laparoscopic fundoplication is a good alternative to medical therapy for those with volume regurgitation or intolerance to medications, but is otherwise not superior and comes with attendant complications, and should thus be reserved for patients who respond to PPIs. On the basis of current data,

**FIG 24.8** Endoscopic image **A**, taken during the creation of a transoral incisionless fundoplication. An over-the-endoscope device is attached and advanced into the stomach. (Photos courtesy Kenneth J. Chang, MD.)

the use of the magnetic sphincter augmentation device appears to be an acceptable alternative to fundoplication in a highly-restricted cohort of patients with nonerosive disease and minimal hiatal herniation, though side effects may become a concern in the future. Future options for the treatment of GERD might include novel medical therapies and incorporate new technology to allow for the endoscopic creation or augmentation of antireflux barriers.

## INTRODUCTION

Barrett's esophagus (BE) is an acquired condition resulting from severe esophageal mucosal injury. It is unclear why some patients with gastroesophageal reflux disease (GERD) develop BE whereas others do not. The diagnosis of BE is established if the squamo-columnar junction is displaced more than 1 cm proximal to the esophagogastric junction, and intestinal metaplasia is detected by biopsy.<sup>1</sup> BE would be of little importance if not for its well-recognized association with esophageal adenocarcinoma (EAC). The incidence of EAC continues to increase, and the 5-year survival rate for this cancer remains very poor.<sup>2</sup> However, the overall disease burden of esophageal cancer and cancer risk for an individual patient with BE remains low.

Current strategies for improved survival in patients with EAC focus on cancer detection at an early and potentially curable stage. Early detection can be accomplished either by screening more patients for BE, or with endoscopic surveillance of patients with known BE. However, current screening and surveillance strategies are inherently expensive, inefficient, and of unproven benefit. New techniques to improve the efficiency of cancer surveillance continue to evolve and hold promise to change clinical practice in the future. Treatment options include aggressive acid suppression, antireflux surgery, and chemoprevention with endoscopic eradication therapy reserved for patients with dysplasia or early EAC.

## EPIDEMIOLOGY

The incidence of BE has increased markedly since the 1970s. This increase was previously thought to be due to the increased use of diagnostic upper endoscopy combined with the change in the definition of BE to include shorter segments of columnar-lined epithelium. However, more recent data from a Northern

Ireland population based study found that the incidence of BE has increased from 23.9/100,000 between 1993 and 1997 to 62.0/100,000 between 2002 and 2005.<sup>3</sup> These findings have also been encountered in the Netherlands and Australia.<sup>4,5</sup>

It is estimated that BE is found in approximately 5% to 15% of patients undergoing endoscopy for symptoms of GERD. Population-based studies suggest that the prevalence of BE is approximately 1.3% to 1.6%.<sup>6</sup> Interestingly, most of these patients in the general population have short segments of BE, and approximately 45% have no reflux symptoms. The prevalence of BE in white men increases with age until a plateau is reached at approximately age 50.<sup>7</sup>

Various risk factors have been identified for the presence of BE, including frequent and long-standing reflux episodes, erosive esophagitis, smoking, male gender, white race, older age, central obesity, absence of *H. pylori* infection and absence of statin use.<sup>8-13</sup> Familial aggregation of BE is seen in less than 10% of patients with BE and is felt to be caused by an incompletely penetrant autosomal dominant genetic variant.<sup>14</sup> Genome wide association studies have also identified several candidate susceptibility loci for BE.<sup>15</sup>

## DIAGNOSIS

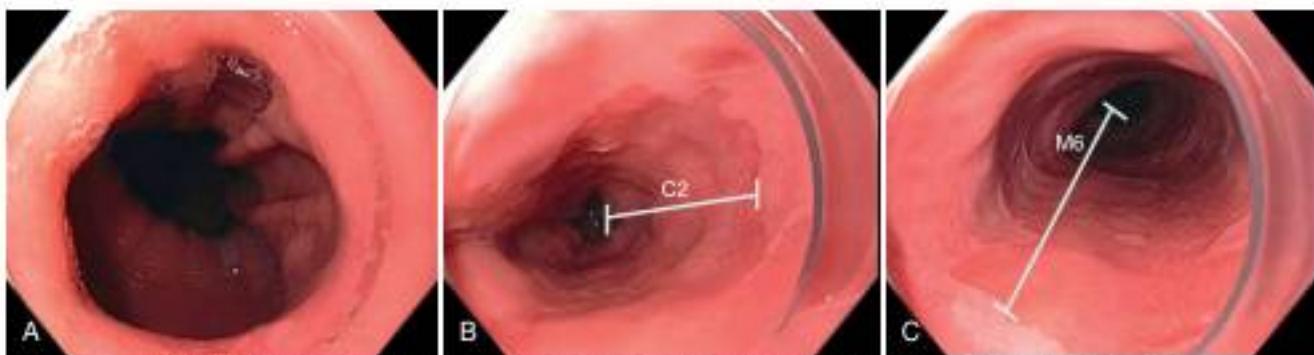

BE is currently best defined as a metaplastic change in the lining of the tubular esophagus extending more than 1 cm above the gastroesophageal junction with biopsy confirmation of intestinal metaplasia.<sup>1</sup> Endoscopically, this metaplastic change is characterized by displacement of the squamocolumnar junction proximal to the esophagogastric junction defined by the proximal margin of gastric folds (Fig. 25.1). At the time of endoscopy, landmarks should be carefully identified, including the diaphragmatic pinch, the esophagogastric junction as best defined by the proximal margin of the gastric folds seen on partial insufflation of the

**Abstract**

Barrett's esophagus (BE) is an acquired condition resulting from gastroesophageal reflux disease and is a well-established risk factor for esophageal adenocarcinoma (EAC). The diagnosis of BE is established if the squamocolumnar junction is displaced 1 cm or more proximal to the esophagogastric junction, and intestinal metaplasia is detected by biopsy. Current strategies for improved survival in patients with EAC focus on cancer detection at an early and potentially curable stage. Early detection can be accomplished either by screening patients for BE or with endoscopic surveillance of patients with known BE. Current professional society practice guidelines recommend considering screening in selected patients at high risk for BE and surveillance in patients diagnosed with BE. Current strategies to enhance surveillance include use of standardized endoscopic grading systems, cognitive knowledge in detection of neoplastic lesions, and use of high-definition, white light endoscopy. However, current screening and surveillance strategies are inherently expensive, inefficient, and of unproven benefit. New techniques to improve the efficiency of screening and surveillance continue to evolve and hold promise to change clinical practice in the future. Treatment options include aggressive acid suppression, antireflux surgery, and chemoprevention with endoscopic eradication therapy reserved for patients with dysplasia or early EAC. The recent shift from volume-based to value-based practice in the United States and variability in quality of care have provided the impetus for defining quality indicators in the diagnosis and management of patients with BE. Adherence to these has the potential to improve quality of care, reduce variability in health-care and ultimately improve patient outcomes.

esophagus, and level of the squamocolumnar junction. It is commonly accepted that the proximal margin of the gastric folds is the most useful landmark for the junction of the stomach and the esophagus.<sup>16</sup> However, the precise junction of the esophagus and the stomach may be difficult to determine endoscopically because of the presence of a hiatal hernia, the presence of inflammation, and the dynamic nature of the esophagogastric junction, all of which may make targeting of biopsy specimens problematic.

Endoscopists identify landmarks necessary for the diagnosis of the columnar-lined esophagus inconsistently (see Fig. 25.1)<sup>17</sup>; this leads to inconsistencies in the diagnosis of BE. The Prague classification was developed to standardize the description of BE. This classification scheme describes the circumferential extent (C value) and maximum extent (M value) of columnar mucosa above the proximal margin of the gastric folds (see Fig. 25.1).<sup>18</sup> The Prague classification does not include columnar islands; however, reliability coefficients for both criteria for segments greater than 1 cm in length, as well as for other endoscopic landmarks, including the diaphragmatic hiatus and proximal margin of the gastric folds, are excellent. Recognition of less than 1 cm of columnar metaplasia even with this scoring system is still problematic, pointing out the difficulties in measuring such short segments. The Prague classification has been validated in clinical settings in North America, Europe, and Asia.<sup>18–21</sup>

If the squamocolumnar junction is 1 cm or more above the level of the esophagogastric junction, as defined by the proximal margin of the gastric folds using partial insufflation, biopsy specimens should be obtained for confirmation of intestinal metaplasia. There is ongoing debate regarding the need for intestinal metaplasia for the diagnosis of BE. The professional societies of North America all require intestinal metaplasia for the diagnosis of BE, whereas the British Society of Gastroenterology does not require the presence of intestinal metaplasia for the diagnosis.<sup>22</sup> Although one study suggested that nongoblet cell columnar metaplasia shows DNA content abnormalities indicative of neoplastic risk similar to neoplasia encountered in intestinal metaplasia, a large population based study from Northern Ireland found that the risk of EAC was higher in patients with intestinal metaplasia than in those without.<sup>21,24</sup>

How many biopsy specimens are needed to detect intestinal metaplasia? Detection of intestinal metaplasia is related to several factors, including location of biopsies, length of columnar-lined segment, number of biopsy specimens obtained, male gender, and increasing age.<sup>25,26</sup> Intestinal metaplasia is more commonly

found in biopsy specimens obtained in the proximal portion of the columnar-lined esophagus where goblet cell density is also greater.<sup>27</sup> Data suggests that the detection of intestinal metaplasia increases with increasing number of biopsy specimens per endoscopy; four biopsy specimens have a yield of 34.7%, whereas eight biopsy specimens have a yield of 94% for intestinal metaplasia.<sup>28</sup> Taking more than eight biopsy specimens does not seem to enhance the yield of intestinal metaplasia. This has led the current iteration of the American College of Gastroenterology Barrett's Esophagus (ACG BE) guidelines to suggest obtaining a minimum of eight biopsies to maximize the yield of intestinal metaplasia.<sup>1</sup>

It may be difficult to determine endoscopically where the esophagus ends and the stomach begins for the reasons outlined earlier. It is impossible to reliably distinguish columnar metaplasia of the distal esophagus from columnar metaplasia of the stomach. All current practice guidelines and quality metrics recommend that biopsy specimen of the normal squamocolumnar junction should not be routinely obtained in clinical practice if it is at the level of the esophagogastric junction.<sup>1</sup> Several studies indicate that cancer risk of intestinal metaplasia of the normal gastroesophageal junction is substantially lower compared to those with BE and thus that routine biopsies should not be obtained.<sup>30,31</sup>

## SCREENING

Only 5% to 7% of patients newly diagnosed with EAC have undergone endoscopy and received a prior diagnosis of BE.<sup>32,33</sup> As such, surveillance of patients with BE would be expected to have limited impact on the 95% of EAC patients who are not known to have BE. One potential strategy to decrease the mortality rate of EAC is to identify more patients at risk, namely those with BE. Population-based studies suggest that in patients with newly diagnosed EAC, a prior endoscopy and diagnosis of BE are associated with both early stage cancer and improved survival.<sup>34</sup> Current professional society practice guidelines now all recommend considering screening for BE in selected patients at high risk for BE. The target population includes patients with chronic GERD symptoms and one or more risk factors including male gender, age over 50 years, Caucasian ethnicity, central obesity, and a positive family history of BE or EAC.<sup>1,22,34,36</sup>

High-definition white light endoscopy (HD-WLE) with biopsy is still the only validated technique to diagnose BE. However, it has clear limitations as a screening tool, including cost, risk, complexity, and diagnostic inconsistencies. For example, a 2014

study found that only 68% of patients diagnosed with BE in the community had confirmed BE, whereas the remainder had the diagnosis of BE reversed due to the absence of a columnar lined esophagus, intestinal metaplasia, or both.<sup>37</sup> If screening with endoscopy and biopsy were applied to the estimated 20% of the population with regular GERD symptoms, the cost implications would be staggering. Unsedated upper endoscopy using small-caliber instruments still has the potential to change the economics of endoscopic screening because this technique may decrease sedation-related complications and costs. Unsedated small-caliber endoscopy detects BE and dysplasia with sensitivity comparable to conventional endoscopy.<sup>38</sup> Although both procedures are well tolerated by patients, a major hurdle for unsedated endoscopy is continued patient resistance to undergoing a test without sedation. Otherwise, there are still no validated alternative techniques to screen for BE that overcome the cost and risks associated with conventional upper endoscopy.

There is clearly a need to develop either a better profile of patients at high risk for BE or a far less expensive tool to provide mass population screening. A variety of risk prediction models have been studied to accomplish this by examining risk factors such as frequency and duration of GERD symptoms, age, smoking, waist to hip ratio, *H. pylori* status, and inflammatory cytokines.<sup>39-41</sup> Models that include variables in addition to GERD frequency show encouraging performance characteristics but need further validation prior to application into clinical practice.

A variety of alternatives to both sedated and unsedated endoscopy are also now under investigation around the world. Much interest is directed at a nonendoscopic Cytospunge currently undergoing clinical trials. This Cytospunge capsule, administered by a nonphysician in an outpatient setting, had a sensitivity of 80% for BE and a specificity of 92% in a United Kingdom trial.<sup>41</sup> Another nonendoscopic device under study is tethered endomicroscopy, but data to date are limited.<sup>42</sup> Exciting new screening strategies based on the microbiome and exhaled volatile organic compounds are also under study.<sup>43-44</sup>

After a normal initial upper endoscopy, some clinicians wonder if a repeat screening upper endoscopy should be undertaken in symptomatic GERD patients at a later date. Several studies have addressed this point with consistent results. In patients with nonerosive reflux disease at the index endoscopy, BE is rarely found if the repeat endoscopy is performed within 5 years.<sup>45-48</sup> BE may be present in 9% to 12% of patients with erosive esophagitis at the time of index endoscopy, and higher grades of esophagitis are associated with a higher case finding rate of BE on repeat endoscopy.<sup>47-48</sup> Screening for BE in GERD patients should take place only after initial therapy with a proton pump inhibitor (PPI). A negative endoscopy at baseline makes it highly unlikely to find BE if endoscopy is repeated.

There are still no data from randomized controlled trials or observational studies to evaluate the strategy of screening. A decision analysis model by Inadomi et al (2009) examined screening of 50-year-old white men with chronic GERD symptoms for BE and found that one-time screening is probably cost-effective if subsequent surveillance is limited to patients with dysplasia on initial examination.<sup>49</sup> This strategy would result in a cost of \$10,440 per quality-adjusted life year saved compared with a strategy of no screening or surveillance. Other modeling studies support screening in patients with chronic GERD symptoms as well, but only if the following conditions are met: patients at high risk for BE, high-grade dysplasia (HGD), or EAC; high sensitivity and specificity of endoscopy with biopsy; and little

or no reduction in quality of life with esophagectomy.<sup>50,51</sup> Any variation of these ideal conditions quickly made this strategy cost-ineffective. Problems inherent in showing the utility of a screening program, such as healthy volunteer bias, lead time bias, and length time bias, all need to be addressed.

## SURVEILLANCE

### Rationale for Surveillance

Current practice guidelines recommend endoscopic surveillance of patients with BE in an attempt to detect cancer at an early and potentially curable stage.<sup>1,22,52</sup> Numerous observational studies suggest that patients with BE in whom EAC was detected in a surveillance program have their cancers detected at an earlier stage with markedly improved 5-year survival compared with similar patients not undergoing routine surveillance.<sup>53-57</sup> Because survival in EAC is stage-dependent, these studies suggest that survival may be enhanced by endoscopic surveillance. Several decision-analysis models support the concept of endoscopic surveillance.<sup>51,58</sup> Four recent population-based studies (2013–16) evaluated the impact of surveillance in patients with BE. A large Northern Ireland population-based study showed that in patients with EAC and a prior diagnosis of BE, survival was improved and tumor stage and grade was lower compared with patients without a prior diagnosis of BE.<sup>53</sup> Similarly, a large Dutch population-based study confirmed survival advantage for EAC in patients who were in surveillance programs compared with patients who were not a part of surveillance programs.<sup>54</sup> A cohort study of patients with BE diagnosed in the National Veterans Affairs hospitals showed that surveillance endoscopy was associated with an early stage diagnosis of EAC, longer survival, and decreased overall and cancer-related mortality.<sup>55</sup> On the other hand, a case-control study from the Northern California Kaiser Permanente population found no evidence that endoscopic surveillance improved survival from EAC.<sup>56</sup> Despite the variable results and lack of data from randomized controlled trials comparing surveillance versus no surveillance (not likely to be performed in the future), surveillance of BE patients is recommended.

### Candidates for Endoscopic Surveillance

Patients with documented BE are candidates for surveillance. Before entering a surveillance program, patients should be advised about risks and benefits, including the limitations of surveillance endoscopy and the importance of adhering to appropriate surveillance intervals.<sup>1</sup> Other considerations include age, likelihood of survival over the next 5 years, and ability to tolerate either endoscopic/surgical interventions or medical/radiation oncologic treatments for EAC.

### Surveillance Technique

The aim of surveillance is to detect dysplasia. The revised Vienna classification for gastrointestinal (GI) mucosal neoplasia and the World Health Organization (WHO) classification of GI tumors are the most commonly utilized grading systems to categorize patients with and without dysplasia in BE.<sup>52,53</sup> Dysplasia is described as negative for dysplasia, indefinite for dysplasia, low-grade dysplasia (LGD), HGD, and carcinoma. Active inflammation makes it more difficult to distinguish dysplasia from reparative changes. It is essential that surveillance endoscopy is performed only after any active inflammation related to GERD is controlled with antisecretory therapy. The presence of ongoing erosive

esophagitis is a contraindication to performing surveillance biopsies. Current guidelines suggest obtaining systematic four-quadrant biopsies at 2-cm intervals along the entire length of the Barrett's segment after inflammation related to GERD is controlled.<sup>6</sup> A systematic biopsy protocol clearly detects more dysplasia and early EAC compared with ad hoc random biopsies.<sup>6,7</sup> The "turn and suction" technique allows acquisition of biopsy specimens that are significantly larger than the specimens obtained by the traditional techniques of advancing an open biopsy forceps into the lumen and then closing it to obtain the biopsy sample.<sup>8</sup> The safety of systematic endoscopic biopsy protocols has been demonstrated.<sup>9</sup> Separate biopsies of subtle mucosal abnormalities, no matter how trivial, such as ulceration, erosion, plaque, nodule, stricture, or other luminal irregularity in the BE segment should be performed, given the association of such lesions with underlying cancer.<sup>10</sup> Patients with mucosal abnormalities should undergo endoscopic mucosal resection (EMR). EMR will change the diagnosis in approximately 50% of patients when compared with endoscopic biopsies, given the larger tissue sample available for review, and will result in an improvement in interobserver agreement among pathologists.<sup>11,12</sup> The role of wide-area transepithelial sampling using a minimally invasive brush biopsy technique for acquiring wide-area sampling of BE followed by computer-assisted analysis needs to be further elucidated in future trials.<sup>13</sup>

### Surveillance Intervals

Surveillance intervals are determined by the presence and grade of dysplasia and based on expert opinion given the limited understanding of the biology of EAC. Current guidelines recommend surveillance endoscopy at 3 to 5 year intervals in patients with BE without dysplasia given the low risk of progression of BE to EAC.<sup>1,2,3,4,5,7,14</sup> In BE patients diagnosed with LGD, the diagnosis of LGD should be confirmed by an expert GI pathologist given the significant interobserver variability among pathologists.<sup>15</sup> Patients in whom the diagnosis of LGD is downgraded to nondysplastic BE should be managed as nondysplastic BE. In patients with confirmed LGD, repeat upper endoscopy using HD-WLE should be performed under maximal acid suppression in 8 to 12 weeks. Surveillance biopsies should be performed in a 4-quadrant fashion every 1 to 2 cm with targeted biopsies from visible lesions. Ideally, EMR should be performed in patients with endoscopically visible lesions (no matter how subtle). In patients with confirmed BE with LGD that persists on a second endoscopy, risks and benefits of management options of endoscopic eradication therapy and ongoing surveillance should be discussed and documented. Patients with LGD undergoing surveillance rather than endoscopic eradication therapy should undergo surveillance every 6 months ( $\times 2$ ), then annually unless there is reversion to BE without dysplasia.<sup>16</sup> If HGD is found, the diagnosis should first be confirmed by an expert GI pathologist. EMR should be performed if a visible lesion is identified. If HGD is confirmed, endoscopic eradication therapy is recommended.

### Limitations of Surveillance

As currently practiced, endoscopic surveillance of BE has numerous shortcomings. Dysplasia and early EAC may be endoscopically indistinguishable from BE without dysplasia. The distribution of dysplasia and early EAC is highly focal and variable, and even the most thorough biopsy surveillance program has the potential for sampling errors. Current surveillance programs are expensive

and time-consuming. Although survey data indicate that surveillance is widely practiced, there is considerable variability in the technique and interval of surveillance and practice guidelines are not widely followed in the community.<sup>17-19</sup> In addition, there is significant interobserver and intraobserver variability among community and expert pathologists in the interpretation of dysplasia.<sup>6,19-21</sup>

### Potential Strategies to Enhance Surveillance

#### Uniform Grading Systems

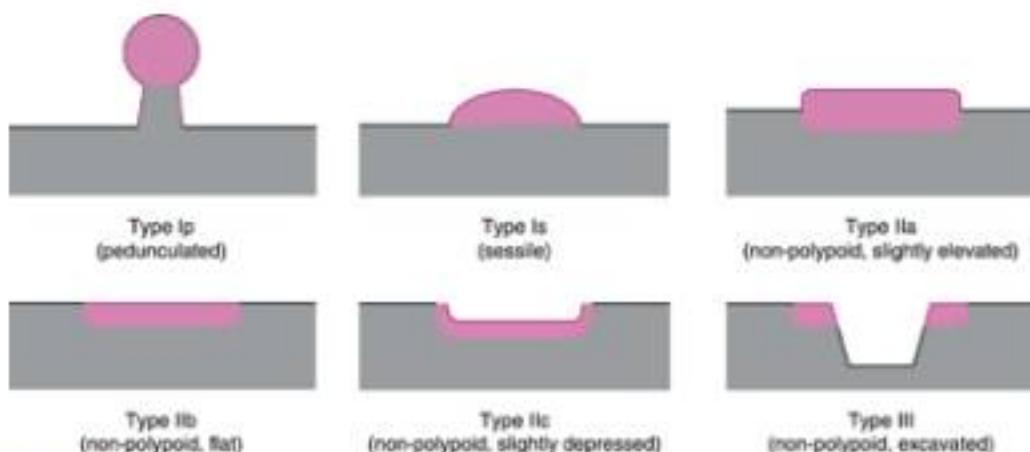

For patients with BE, standardized reporting and grading systems such as the Prague C&M criteria based on the circumferential (C) and (M) extent of the columnar-lined esophagus should be utilized. This system has been extensively validated among experts, nonexperts and trainees.<sup>18,19</sup> All visible lesions identified within the Barrett's segment should be recorded using the Paris classification; protruded lesions are recorded as: 0-Ip (pedunculated) or 0-Is (sessile) and flat lesions are recorded as 0-IIa (superficially elevated), 0-IIb (flat), 0-IIc (superficially depressed), and 0-III (excavated). Lesions classified as 0-Is, 0-IIc, and 0-III are most likely to harbor invasive cancer, whereas 0-IIa and 0-IIb are unlikely to contain invasive cancer (Fig. 25.2).<sup>22</sup> However, the use of the Paris classification as a prognostic tool has not been extensively evaluated in Barrett's related neoplasia. The use of uniform grading systems such as the Prague and Paris criteria help improve communication between endoscopists during endoscopic follow-up and potentially in predicting the presence of invasive cancer and considering endoscopic therapies in appropriate candidates.

#### Cognitive Knowledge, Learning Curves, and Training

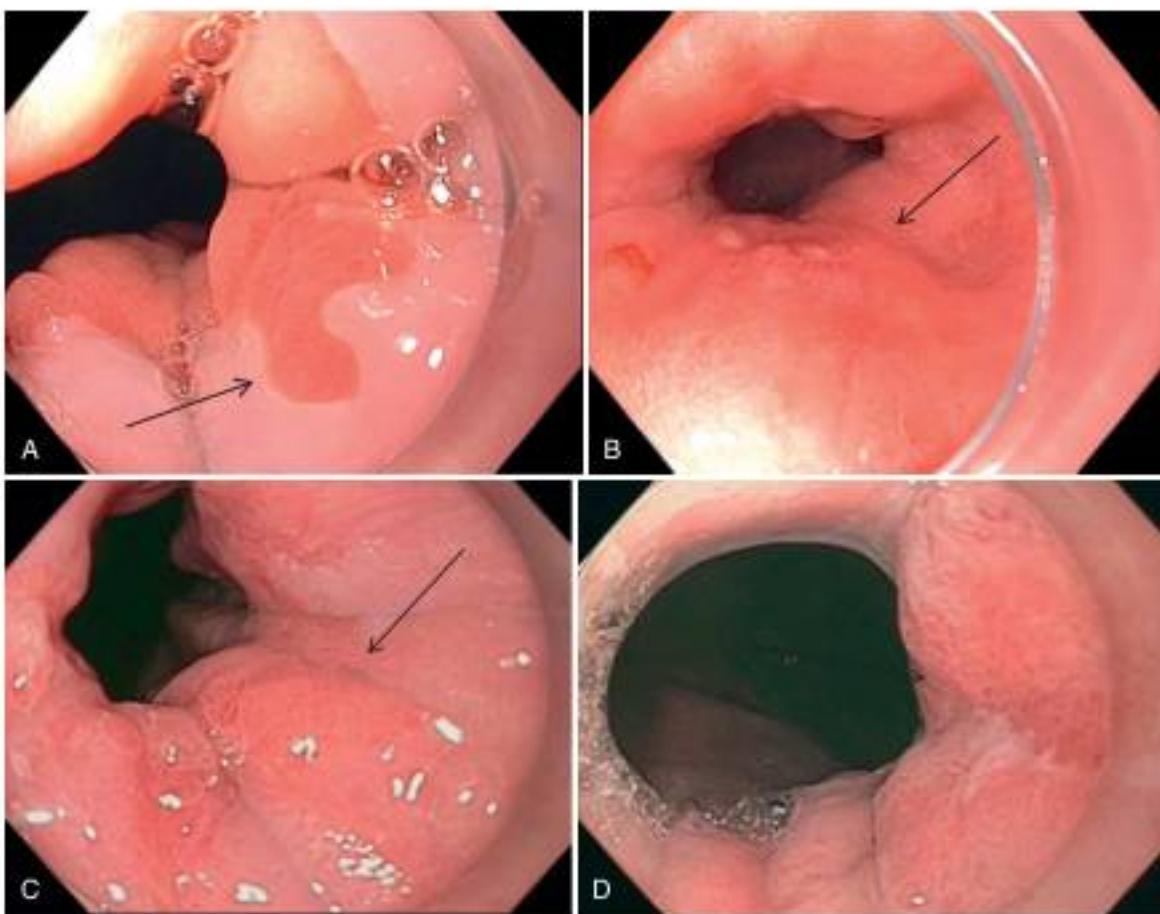

The cognitive knowledge regarding endoscopic appearance of subtle lesions during surveillance endoscopy is critical. These are lesions that harbor esophageal neoplasia at an early stage and are amenable to early, minimally invasive therapies. The appearance of subtle lesions varies widely and can include slight polypoid protrusion or nodularity, ulceration, areas of depression, superficial plaques, or mucosal discoloration. It is important to spend adequate time during upper endoscopy to detect subtle lesions. It has been suggested that inspecting the Barrett's segment for more than one minute per centimeter length of BE is associated with detection of more patients with suspicious lesions, with a trend toward a higher detection rate of HGD or EAC.<sup>23</sup> These findings need to be validated in future studies, especially in low-risk populations undergoing surveillance endoscopy. There are limited data on the learning curves and impact of training in the detection of early neoplasia (with or without advanced imaging techniques). A 2015 study showed that endoscopists trained in BE surveillance (training in Prague classification, Seattle protocol biopsy technique, and lesion detection) with dedicated time slots or lists had higher dysplasia detection rates than a nontrained/specialist cohort.<sup>24</sup> Recent studies have also demonstrated that endoscopists at community hospitals detect neoplastic lesions at a significantly lower rate compared to endoscopists at expert centers.<sup>24,25</sup> These data suggest that surveillance should be performed by trained endoscopists in dedicated endoscopy blocks.

#### Imaging Modalities to Enhance Surveillance

Several imaging modalities have been investigated to improve detection and identification of patients with early neoplastic lesions during routine screening and surveillance endoscopy

**FIG 25.2** Paris Classification for Gastrointestinal Neoplasia. (Modified from Endoscopic Classification Review Group: the Paris endoscopic classification of superficial neoplastic lesions: esophagus, stomach, and colon: November 30 to December 1, 2002. *Gastrointest Endosc* 58[6]: S3–S43, 2003.)

**FIG 25.3** Examples of visible lesions detected at high resolution endoscopy in patients with Barrett's esophagus (arrows pointing to the visible lesions within the Barrett's segment).

and prediction of histology and real-time diagnosis during endoscopy.

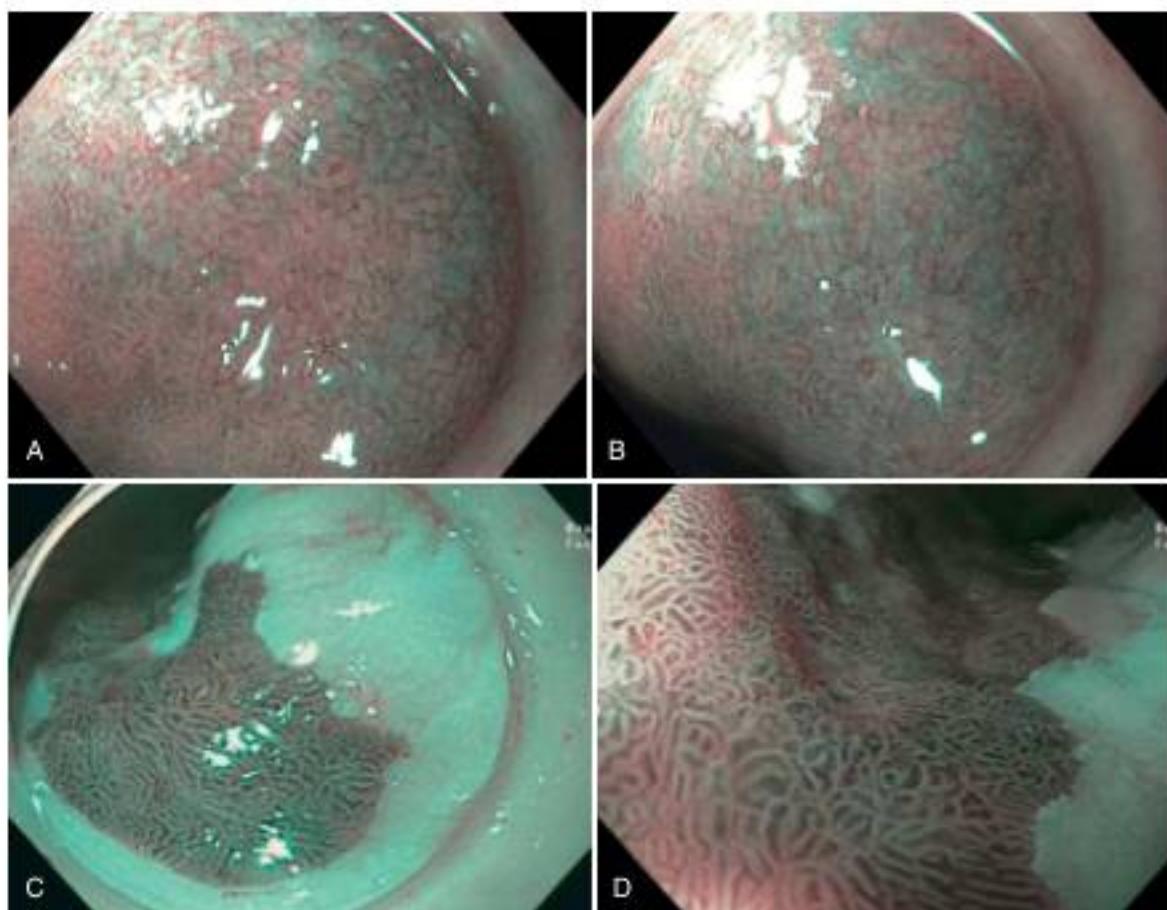

**High-definition white light endoscopy.** Technologic advancements have allowed the creation of smaller charge-coupled device chips that are capable of producing images with high resolution (over 850,000 to 2.1 million pixels) displayed on monitors with a 16:9 aspect ratio and resulting in superior imaging quality

compared to standard definition (SD) WLE. High definition magnification endoscopes can optically magnify images up to 150 times (not available in the United States).<sup>36</sup> The use of HD-WLE should be considered the standard of care and the first critical step in the evaluation of BE patients undergoing surveillance or being considered for endoscopic eradication therapies (Fig. 25.3).<sup>37</sup> Although there is no level 1 evidence in

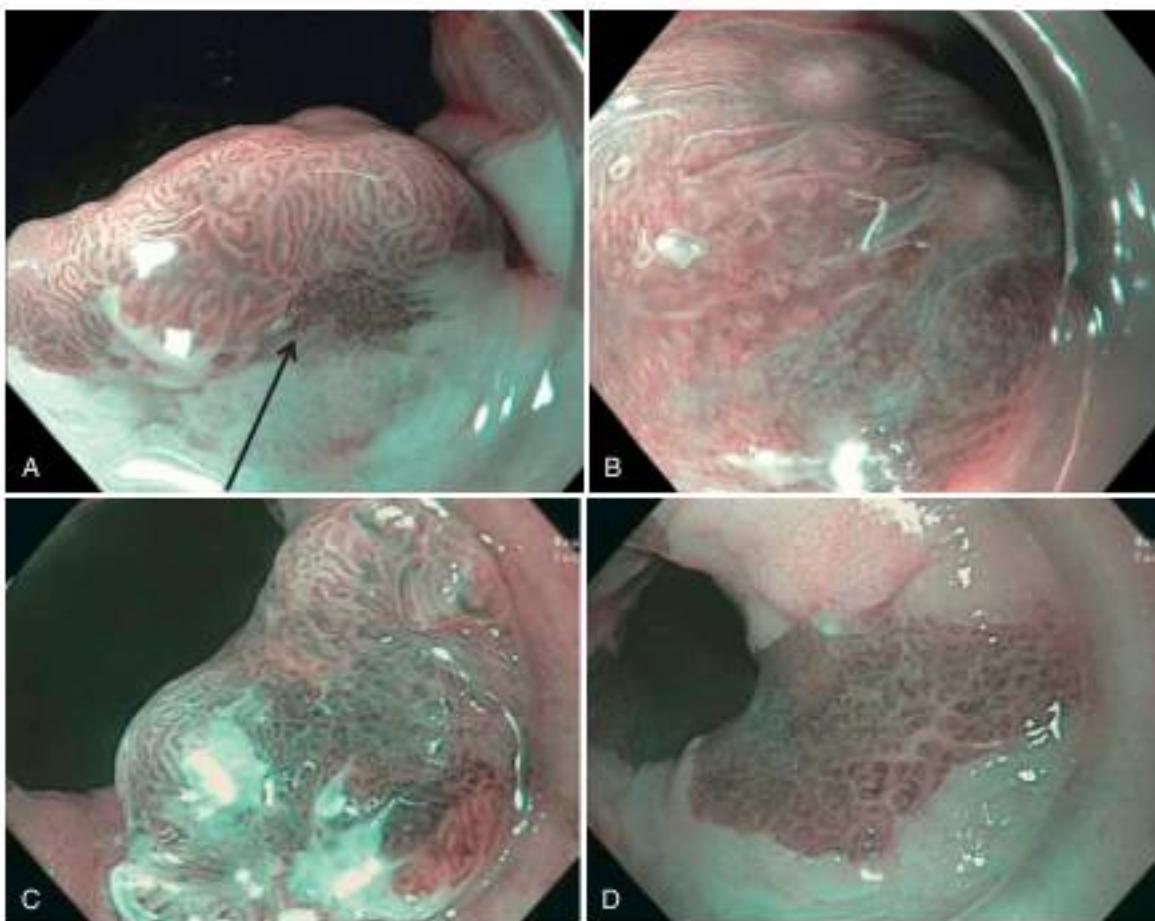

the form of a randomized controlled trial comparing HD-WLE to SD-WLE, this recommendation has been endorsed by guidelines and consensus documents.<sup>32,52,68</sup> Indirect evidence from three prospective trials and a single retrospective study suggests that HD-WLE is more sensitive compared to SD-WLE in the detection of Barrett's related neoplasia.<sup>32,61</sup>

**Optical electronic chromoendoscopy.** This diagnostic modality provides enhanced visualization of the mucosa using light filters and computer processing technology without the need to spray dye. There are three available platforms for optical chromoendoscopy: narrow band imaging (NBI; Olympus, Center Valley, PA), Fujinon intelligent color enhancement (FICE; Fujinon, Wayne, NJ), and i-Scan (Pentax Medical, Montvale, NJ). NBI is an imaging technique that is based on the optical phenomenon that the depth of light penetration into tissue depends on the wavelength; the shorter the wavelength, the more superficial the penetration. Use of blue light with narrow band filters enables detailed imaging of the mucosal and vascular surface patterns with a high level of resolution and contrast without the need for chromoendoscopy.<sup>93</sup> FICE and i-Scan use proprietary post-image acquisition processing technology to modify the white light image, enhancing the superficial mucosal and vascular pattern. Optical chromoendoscopy is easy to use, utilizes "push button" technology, and frequently used as an adjunctive tool to HD-WLE (although the additional benefit in some situations has been debated).

NBI is the most widely studied electronic chromoendoscopy technique and has been evaluated as a tool to predict histology during surveillance, improve detection of dysplasia, and guide endoscopic eradication therapies. Characteristic patterns associated with nondysplastic BE (regular mucosal and vascular pattern) and BE with early neoplasia (irregular mucosal and vascular pattern) have been described using NBI (Figs. 25.4 and 25.5).<sup>94,95</sup> However, no standardized classification system for BE exists. In a 2016 study, an international working group of experts established a classification system (regular vs. irregular mucosal and vascular pattern based on NBI features; Table 25.1) that had an overall accuracy rate of 85.4% (95% confidence interval [CI] 82.6%–87.9%) with higher accuracy rates in images where the endoscopist had a high confidence diagnosis (92.2% [95% CI 89.3%–94.5%]). The overall strength of interobserver agreement was substantial ( $\kappa = 0.68$ ).<sup>95</sup> A prospective tandem study that compared HD-NBI targeted biopsy with SD-WLE targeted with random biopsy showed that NBI increased the per-patient yield of dysplasia, identified higher grades of dysplasia, and required fewer biopsies.<sup>96</sup> This classification system requires external validation among nonexperts and trainees during real-time endoscopy or using video-based assessment. A recent, randomized, multicenter study comparing NBI to HD-WLE demonstrated a comparable detection rate of intestinal metaplasia and early neoplasia with fewer biopsies required in the NBI arm.<sup>97a</sup> In contrast, a 2013 systematic review and meta-analysis showed that advanced imaging techniques

**FIG 25.4** Detailed close (A and B) and overview imaging (C and D) using NBI demonstrating regular mucosal and vascular patterns in patients with nondysplastic Barrett's esophagus.

**FIG 25.5** Examples of early neoplastic lesions demonstrating irregular mucosal and vascular patterns using NBI.

**TABLE 25.1 Consensus-Driven NBI Classification for Identification of High-Grade Dysplasia and Esophageal Adenocarcinoma in Barrett's Esophagus**

Morphologic Characteristics	Classification
<b>Mucosal Pattern</b>	
Circular, ridged/villous, or tubular patterns	Regular
Absent or irregular patterns	Irregular
<b>Vascular Pattern</b>	
Blood vessels situated regularly along or between mucosal ridges and/or those showing normal, long, branching patterns	Regular
Focally or diffusely distributed vessels not following normal architecture of the mucosa	Irregular

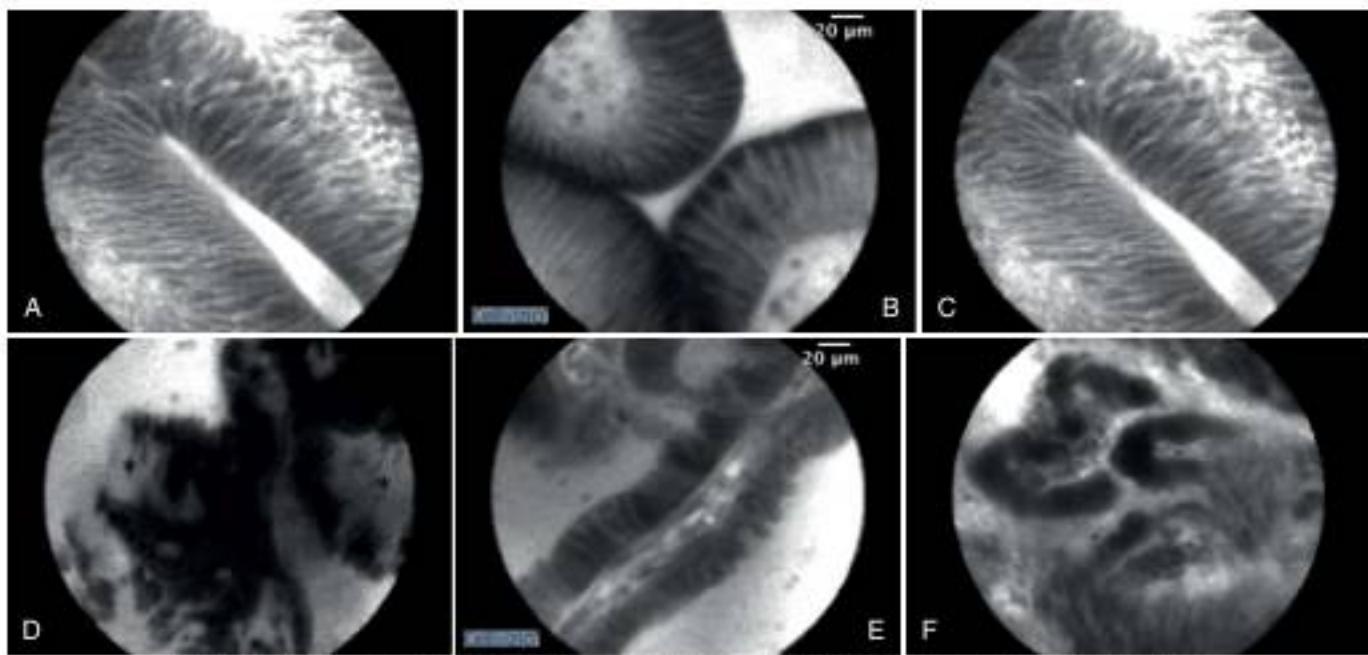

From Sharma P, Bergman JJ, Goda K, et al: Development and validation of a classification system to identify high-grade dysplasia and esophageal adenocarcinoma in Barrett's esophagus using narrow-band imaging. *Gastroenterology* 150(3):591-598, 2016.

(optical chromoendoscopy and chromoendoscopy) increased dysplasia or cancer detection by 34% (95% CI 20%-56%,  $p < 0.0001$ ).<sup>97</sup>

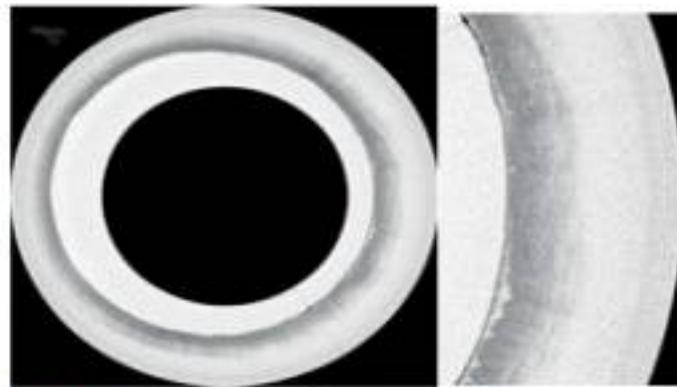

**Chromoendoscopy.** Chromoendoscopy is a technique that involves the spraying of dyes to improve characterization of the

mucosa resulting in selective uptake (vital staining: methylene blue, Lugol's solution) or enhancement of mucosal surface pattern (contrast staining: indigo carmine, acetic acid). It is frequently used in combination with high-resolution and high-magnification endoscopes.<sup>98</sup> A number of initial studies suggested that chromoendoscopy with magnification endoscopy reveals mucosal patterns that correlate with intestinal metaplasia and early neoplasia and may improve detection of the latter. However, a meta-analysis of nine studies concluded that chromoendoscopy with methylene blue did not increase the yield of detecting intestinal metaplasia and dysplasia compared to standard four-quadrant biopsies.<sup>99</sup> Problems associated with the use of chromoendoscopy in clinical practice include the need for dye spraying equipment, difficulty in achieving complete and uniform coating of the mucosal surface with the dye, inability to detect superficial vascular patterns, the time consuming nature of the procedure, conflicting published data, the need for magnification endoscopy, and lack of a standardized classification system. These issues have led to this technique being largely supplanted by optical chromoendoscopy.

**Confocal laser endomicroscopy.** Confocal laser endomicroscopy (CLE) is a technology that has the potential to provide real time histologic visualization of the GI tract. The probe-based system (pCLE) is available commercially with the most extensive published literature. This technology requires the injection of intravenous fluorescein and provides a 240  $\mu\text{m}$  field of view with a range of depth of 55 to 65  $\mu\text{m}$ . Studies have demonstrated

**FIG 25.6** Representative images of confocal laser endomicroscopy in nondysplastic Barrett's esophagus (**A** to **C**) and Barrett's with high grade dysplasia (**D** to **F**).

**FIG 25.7** Volumetric laser endomicroscopy: second generation optical frequency domain imaging that provides high speed and high-resolution images of the entire Barrett's segment, 6 cm at a time, using a balloon imaging catheter.

an improved diagnostic yield for dysplasia in BE patients compared to standard four-quadrant biopsies (Fig. 25.6).<sup>96,100</sup> However, there are several issues with this technology that have limited its widespread adoption in routine clinical practice, such as sampling error associated with the small visual field, increased procedure time and possible decreased efficiency, associated equipment costs, as well as the inconclusive impact of pCLE findings on guiding endoscopic management.

**Future emerging technologies.** Volumetric laser endomicroscopy (VLE, optical frequency domain imaging) is an emerging broad-field imaging technology that provides high-speed real time high resolution images of the entire Barrett's segment (Fig. 25.7). It scans 6 cm of the esophagus over 90 seconds and provides a resolution of 10 μm and an imaging depth of 3 mm.<sup>96,101</sup> The safety and feasibility of this technology was demonstrated in a multicenter trial.<sup>102</sup> A revised scoring system for detection of

dysplasia in BE improved the overall diagnostic characteristics (sensitivity 86%, specificity 88%, and accuracy 87%) using EMR specimens.<sup>103</sup> In a 2017 study that utilized high-quality, ex vivo VLE-histology correlation, the VLE features independently and significantly associated with BE-related neoplasia included layering, surface signal, and irregular glands/ducts. A VLE prediction score for BE neoplasia was developed and validated, with receiver operating curve showing an area under curve of 0.81 (95% CI 0.71–0.90).<sup>104</sup> Future iterations of this device will incorporate laser marking to accurately sample abnormalities seen on imaging. In addition, objective measures such as computer-aided detection are currently being investigated to assist in HD-WLE and VLE and interpretation.<sup>104,105</sup>

High-resolution microendoscopy is a novel imaging modality that allows real-time epithelial imaging at subcellular resolution, and its use has been suggested in conjunction with red flag technologies.<sup>106</sup> Finally, the role of advanced imaging platforms that risk stratify BE patients using fluorescently labeled peptides or lectins needs to be evaluated in future studies.<sup>107,108</sup>

#### Current Status of Real-Time Imaging-Assisted Endoscopic Targeted Biopsy During Surveillance

The American Society for Gastrointestinal Endoscopy (ASGE) Preservation and Incorporation of Valuable Endoscopic Innovations (PIVI) document outlined performance thresholds for an imaging technology with targeted biopsies to eliminate the need for random biopsies during endoscopic surveillance of BE.<sup>109</sup> The established thresholds were as follows: (1) imaging technology with targeted biopsies should have a per-patient sensitivity of 90% or higher and a negative predictive value (NPV) of 98% or greater for detecting HGD or early EAC, compared with the current standard protocol; and (2) the imaging technology should have a specificity that is sufficiently high (80%) to allow a reduction in the number of biopsies (compared with random biopsies). A 2016 meta-analysis assessed the diagnostic characteristics of

**BOX 25.1 Basic Principles and Practical Tips to Improve Detection of Subtle Lesions During Upper Endoscopy**
**Technical**

1. Ensure that the procedure is performed under adequate sedation
2. Use of high-definition endoscopes is the minimum standard for adequate inspection
3. Clean the mucosa using water and/or mucolytic agent (e.g., N-acetylcysteine)
4. Spend adequate time for inspection during endoscopy and obtain multiple endoscopy images
5. Follow a systematic and meticulous approach during inspection
6. Carefully scrutinize the right side of the esophagus (12 to 6 o'clock position) during inspection of the Barrett's segment
7. Inspect gastric mucosa after adequate air insufflation in en-face and retroflexed views
8. Consider the use of a distal attachment cap
9. Clearly document landmarks, location of lesions and use standardized grading systems such as the Prague C&M criteria and Paris classification
10. Biopsies should be based on published guidelines (e.g. Seattle protocol for surveillance of Barrett's esophagus)

**Cognitive**

1. Knowledge of standardized grading systems
2. Training and familiarity of key signs for detecting early neoplasia
3. Training in the use of high-definition white light endoscopy and optical chromoendoscopy

chromoendoscopy using acetic acid and methylene blue, and electronic chromoendoscopy by using NBI and CLE for the detection of dysplasia.<sup>110</sup> This meta-analysis showed that targeted biopsies obtained by expert endoscopists using acetic acid chromoendoscopy (sensitivity 96.6%, NPV 98.3%, specificity 84.6%), NBI (sensitivity 94.2%, NPV 97.5%, specificity 94.4%) and CLE (sensitivity 90.4%, NPV 98.3%, specificity 92.7%) meet the thresholds set by the ASGE PIVI document. That being said, several challenges need to be addressed before these technologies can become part of routine clinical practice and include (1) establishing training programs for detection of early neoplasia that are acceptable and applicable to the broader gastroenterology community; (2) demonstrating that these results can also be obtained by nonexperts; (3) standardization of classification systems for advanced imaging techniques; and finally (4) to set quality indicators for image-guided target biopsies. Until these endpoints are achieved, endoscopists should follow the basic principles outlined in Box 25.1 for improving detection of early neoplasia in BE (see also Video 25.1).

### Biomarkers of Increased Risk of Progression
